N28.5

This book has been manufactured in
accordance with wartime regulations
in every respect.

Printed in United States of America by
KINGSFORD PRESS, KINGSFORD, TENN.

Preface

The wide circulation and enduring usefulness of the first four volumes of this series have led the publishers to ask the Editor to plan two new volumes which would cover more recently developed theories, methods and procedures, as well as new topics or newer aspects of old topics. Following the lines of the earlier volumes, Volume V contains the papers dealing with Theory and Methods, and Biology and Medicine, while Volume VI will contain those dealing with Technological Applications.

War conditions have prevented the Editor from securing, as before, a world-wide representation of nations and nationalities, but the enormous development of American science and technology has enabled him to secure a rather complete and distinguished group of contributors, who represent a variety of national origins. Sincere thanks are due to them all, for without their effort and sacrifice, these books could not have been prepared.

The wide variety of topics considered in this series, and the different modes of approach to the same or interrelated subjects, will, it is hoped, give the user of the books a broader and more integrated view of natural phenomena than is obtainable from treatises of more limited scope. Though the number is naturally incomplete, yet enough of the fragments of the jig-saw puzzle of nature are included to give, when properly placed, some notion as to the beauty, complexity, and interrelation of the principles governing animate and inanimate things. We must not allow the diversities of scientific methods and jargons to obscure the ideas and principles they carry, nor must we allow the glib use of scientific terms to take the place of understanding. As the philosopher Thomas Hobbes truly remarked: "Words are wise men's counters—they do but reckon by them; but they are the money of fools" ("Leviathan").

These books should prove of use to scientists in a wide variety of different fields in attacking ever-recurrent problems. Not only are the data and points of view assembled in the various papers of value in themselves, but the reader is subjected to the influence of knowledge obtained in fields remote from his own; and this has a quickening influence. The all too commonly held notion that a chemical analysis or the isolation of an effective chemical substance is an end in itself vanishes when we consider the highly complicated phenomena of biology and of industry. The more we learn, the greater the problems that confront us; and it is hoped that this series will continue to be of practical value to those seeking solutions of these problems.

Thanks are due to the publishers for their continued coöperation, and to the typesetters, printers, binders and others who carried the burden of fabricating the books; to the various publishers and publications whose courtesy has permitted the reproduction of quotations, facts and figures; and also to the many individuals who gave the Editor help and advice. In each case, the Editor has tried to see that appropriate acknowledgment is made, directly in the text or through the bibliography.

Contents

| | PAGE |
|---|------|
| PREFACE | iii |
| THEORY AND METHODS | |
| CHAPTER | |
| 1. SUCCESSIVE LEVELS OF MATERIAL STRUCTURE—Jerome Alexander | 1 |
| 2. THE SURFACES OF SOLIDS AND LIQUIDS AND THE FILMS THAT FORM UPON THEM —William D. Harkins | 12 |
| 3. SOLUTIONS OF SOAPS AND DETERGENTS AS COLLOIDAL ELECTROLYTES—James W. McBain | 102 |
| 4. APPLICATIONS OF ELECTRON DIFFRACTION—Lester H. Germer | 120 |
| 5. METHODS FOR THE ANALYSIS OF COMPLEX MOLECULAR STRUCTURES WITH THE AID OF X-RAYS—Maurice L. Huggins | 131 |
| 6. MICRORADIOGRAPHY OF COLLOIDAL MATERIALS—George L. Clark | 146 |
| 7. THE ELECTRON MICROSCOPE—Albert F. Prebus | 152 |
| 8. RHEOLOGICAL PROPERTIES OF SIMPLE AND COLLOIDAL SYSTEMS—Henry Eyring and Richard E. Powell | 236 |
| 9. HIGH-VACUUM DISTILLATION—K. C. D. Hickman | 253 |
| 10. STATES OF AGGREGATION OF SOME PARAFFIN CHAIN COMPOUNDS—Robert D. Vold and Marjorie J. Vold | 266 |
| 11. POLYMERIZATION—H. Mark | 280 |
| 12. FUNDAMENTAL ASPECTS OF THE ELASTICITY OF RUBBER AND OF RUBBERLIKE MA- TERIALS—Eugene Guth | 286 |
| 13. THE VITREOUS STATE—Maurice L. Huggins, Kuan-Han Sun and Alexander Silverman | 308 |
| 14. SOME IRREVERSIBLE EFFECTS OF HIGH MECHANICAL STRESS—P. W. Bridgman . | 327 |
| 15. SONIC AND ULTRASONIC WAVES IN COLLOID CHEMISTRY—Karl Sollner | 337 |
| 16. THE CYCLOTRON AND SOME OF ITS USES—Jerome Alexander | 373 |
| 17. THE BETATRON: A GENERATOR FOR HIGH-ENERGY ELECTRONS AND X-RAYS— D. W. Kerst | 380 |
| 18. THE ELECTROPHORETIC STUDY OF PROTEINS AND RELATED SUBSTANCES—Duncan A. MacInnes and Lewis G. Longworth | 387 |
| 19. HIGH-SPEED CENTRIFUGATION—E. G. Pickels | 411 |
| 20. MEASUREMENT OF THE SURFACE AREAS OF FINELY DIVIDED AND POROUS MA- TERIALS BY LOW-TEMPERATURE ADSORPTION ISOTHERMS—P. H. Emmett | 434 |
| 21. ADSORPTION AND CRYSTAL HABIT MODIFICATION—Wesley G. France | 443 |
| 22. SOME APPLICATIONS OF SELECTIVE ADSORPTION AND DIFFERENTIAL DIFFUSION IN CHEMICAL ANALYSIS—Beverly L. Clarke | 457 |

| CHAPTER | PAGE |
|---|------|
| 23. COLLOID CHEMICAL ASPECTS OF PHOTOGRAPHIC DEVELOPMENT—S. E. Sheppard . | 472 |
| 24. LIESEGANG RINGS—Andrew Van Hook | 513 |
| 25. FIXING THE DATES OF PAST EVENTS BY TREE RINGS AND VARVES—Chester A. Reeds | 519 |

BIOLOGY AND MEDICINE

| | |
|---|------|
| 26. PROTEINS—W. T. Astbury | 529 |
| 27. CATALYSIS AS A BIOLOGICAL FACTOR—Jerome Alexander | 545 |
| 28. PHOTOSYNTHESIS—Paul Rothemund | 600 |
| 29. PLANT CELL MEMBRANES—Wanda K. Farr | 610 |
| 30. RECENT ADVANCES IN STARCH CHEMISTRY—R. M. Hixon and R. E. Rundle . . | 667 |
| 31. ENZYMES AND THE BIOLOGICAL ACTION OF VITAMINS—A. E. Axelrod and C. A. Elvehjem | 683 |
| 32. MINERALS AND VITAMINS IN APPLIED NUTRITION—Lela E. Booher | 707 |
| 33. THE MECHANISM OF HORMONE ACTION—Oliver Kamm and D. K. Kitchen . . | 739 |
| 34. THE MOLECULAR ORGANIZATION OF VISUAL PROCESSES—George Wald | 753 |
| 35. CHEMICAL PACEMAKERS AND PHYSIOLOGICAL RHYTHMS—Hudson Hoagland . . | 762 |
| 36. THE COLLOID CHEMISTRY OF PURIFIED VIRUSES—Max A. Lauffer and W. M. Stanley | 785 |
| 37. THE GENE—A STRUCTURE OF COLLOIDAL DIMENSIONS—Jerome Alexander . . | 808 |
| 38. THE GENE AS A CHEMICAL UNIT—Jack Schultz | 819 |
| 39. COLLOID CHEMISTRY IN EMBRYONIC DEVELOPMENT—L. G. Barth | 851 |
| 40. THE PHYSICAL STATES OF PROTOPLASM COMPATIBLE WITH LIFE—B. J. Luyet . . | 859 |
| 41. SOME PHYSICAL PROPERTIES OF PROTOPLASM—Robert Chambers | 864 |
| 42. SOME SURFACE-CHEMICAL PROPERTIES OF PROTOPLASMIC PROTEINS—M. J. Kopac | 875 |
| 43. PHYSICAL CHANGES OF MUSCLE RELATED TO ACTIVITY—Otto Meyerhof . . . | 883 |
| 44. THE CAPILLARY CIRCULATION—E. M. Landis | 900 |
| 45. BIOCHEMICAL AND PHYSIOLOGICAL MECHANISMS IN INFLAMMATION—Valy Menkin | 917 |
| 46. THE MODERN OUTLOOK ON BLOOD COAGULATION—John H. Ferguson | 951 |
| 47. IMMUNOLOGY—William C. Boyd | 957 |
| 48. ALLERGY AND ANAPHYLAXIS—Carl A. Dragstedt | 979 |
| 49. HOMEOSTASIS: THE MAINTENANCE OF STEADY STATES IN THE ORGANISM—Walter B. Cannon | 985 |
| 50. THE CAUSES AND NATURE OF CANCER—Leo Loeb | 995 |
| 51. GERONTOLOGY: THE HOW AND WHY OF AGEING—A. J. Carlson | 1051 |
| 52. THE FORMATION OF CONCRETIONS—L. Lichtwitz | 1063 |
| 53. AERO-EMPHYSEMA AND CAISSON DISEASE, A PROBLEM OF COLLOID CHEMISTRY—Jean Piccard | 1082 |
| 54. THE ACTION OF WAR GASES—Chauncey D. Leake and David F. Marsh . . . | 1094 |

Part I
Theory and Methods

Successive Levels of Material Structure

JEROME ALEXANDER

The tangible things with which we deal in our daily lives, and even the much smaller units revealed by our microscopes, ultramicroscopes, electron microscopes and x-ray spectrometers, are complexes resulting from the aggregation of still smaller units at successively lower structural levels. William S. Gilbert put a profound truth into the song of "Little Buttercup" when he wrote: "Things are seldom what they seem."

In the early days of science, its great leaders were termed natural philosophers, for their breadth of view was sufficiently wide to enable them to understand, appraise, correlate and extend existing knowledge of natural phenomena in many fields. As the increasing armies of scientists were deployed over an ever-extending scientific terrain, they accumulated masses of detailed information, much of which was reported in localized scientific dialects, buried in *oubliette* journals, and unappreciated by the comparatively few generalists who remained at scientific headquarters. Specialists in various fields developed their own scientific journals and jargon. Botany and zoölogy were estranged. Chemistry and physics became different disciplines and each spawned a numerous progeny of subsidiary sciences. In medicine the general practitioner, who treated whatever ills his patients happened to have, was overshadowed by a host of highly trained specialists who often found patients suffering with the particular ills they treated. This often saved patients; but it might happen that an opera singer could have a hemorrhage on the stage if a throat specialist failed to recognize active lung trouble.

The reaction from over-specialization in science has been steadily proceeding, not by abolition of the special fields and their journals, but by an increasing appreciation of the close and inseparable interrelations among all scientific disciplines. Nature is oblivious of the subdivisions of knowledge created by university departments, by textbooks, or by any hiatus in personal information. A single natural phenomenon, *e.g.*, respiration, may cross the frontiers of biology, physics, organic, inorganic and colloid chemistry. Although this is well known, it all too frequently occurs that specialists whose attention is focused on conditions or happenings at some one structural level, or even limited to that level, fail to notice or fairly to appraise the relations of what they see to facts emerging at other structural levels. Because of educational hysteresis, rapidly advancing scientific discovery is generally far in advance of textbooks, and because of intellectual inertia it is all too often considerably in advance of teachers. Joint meetings and symposia, the development of borderline sciences, reviews and books of broad scope, and splendidly organized and comprehensive abstract journals, offer to all who are willing to make the effort the means of extending both the area and depth of their scientific vision.

Science and Philosophy

Knowledge of isolated facts, important though they may be, cannot be considered as *science*, although legal Latin terms *scienter* mere knowledge of facts that fix responsibility on an individual. The further we go in our efforts to correlate and colligate facts in various fields, the more closely do we approach *philosophy*, which deals with knowledge of the highest generality, *science* representing the intermediate steps of partially unified knowledge. Laboratory apparatus used to be termed "philo-

sophical instruments," when scientists were "natural philosophers." The "Philosophical Transactions of the Royal Society" and the "Transactions of the American Philosophical Society" contain papers in a wide variety of scientific fields. John Dalton, who was the first Secretary of the Manchester Literary and Philosophical Society, was the discoverer of color blindness* from which he suffered, as well as of the law of chemical combination in fixed proportions. It would be unfortunate if scientific specialists who tolerate brethren in remote fields should adopt a supercilious attitude toward philosophers, who put the hard-won facts of science to the uses for which they are intended—further unification. The motto of Phi Beta Kappa, "Philosophy is the guide or steersman of life," applies cogently to science.

In dealing with ultimate scientific ideas, Herbert Spencer¹ points out that we can form no real concept of an ultimate unit or particle. To say that matter is infinitely divisible commits us to a supposition not realizable in thought. The other alternative, that matter is *not* infinitely divisible, cannot be represented in thought; for every material unit, despite its minuteness, must be thought of as having a top and bottom and a right and left side, like any larger particle, so that a plane of section can be conceived of between them. Considering motion, if we try to follow mentally the decreasing velocity of a rising pendulum, we cannot pass, in thought, from infinitesimally slow motion to *no* motion. The infinitesimal calculus overcomes this impasse by assuming that motion proceeds in a quantum or dropwise fashion, and that there is a sudden minute jump from $v = ds$ to $v = 0$.²

Similarly, we can have no notion as to the limits of space. We cannot imagine that space ends with the so-called Einsteinian Universe, estimated at 2×10^9 light-years, a light-year being approximately six million million miles. This estimate is based on our inability to *measure* any greater distance with the aid of light, the only measuring rod at present available. The fact that we cannot *measure* relative velocities greater than the speed of light does not mean that no such velocities exist. As Soddy pointed out,³ if two particles (electrons) are shot out from a radioactive body in opposite directions and at speeds approximating the speed of light (say nine-tenths c), their motion relative to each other ($1.8c$) would be nearly double the velocity of light. As E. Cunningham⁴ observed, "This is quite true, and the principle of relativity has nothing to say against it. The principle maintains that a velocity greater than c (the velocity of light) *relative to the observer* cannot be observed. . . . The position is not that velocities greater than c are not conceivable, but that real bodies become illusory in observation if they are conceived of to be moving faster than light."

The Relativity of All Knowledge

Spencer devotes the fourth chapter of his "First Principles" to a discussion of "the relativity of all knowledge," and was thus a philosophical precursor of Albert Einstein who demonstrated the relativity of physical measurements. Lest we be too confident of all our sensory knowledge, let it be recalled that Blakeslee and Fox⁵ demonstrated that the ability of persons to taste phenylthiocarbanid is heritable as a Mendelian recessive, and that even those who get any taste at all from it (about 70 per cent) describe it variously as bitter, sweet, salty, or sour. This indicates that there is a relativity of sense impressions. H. C. Moir⁶ tested sixty persons as to their ability to recognize by taste four simple flavors—orange, lemon, lime, and vanilla. Only one person had a perfect score. Five had records of over 75 per cent, but forty-eight failed to reach 50 per cent. Vanilla was variously identified as black currant, lime, apricot, greengage, damson, lemon, pineapple, orange, tangerine, almond, red currant, strawberry.† Only a limited number of persons can taste sodium

* Also known as Daltonism.

† Chemists handling products sold to the public must be sure that their senses for color, taste, odor, and touch are "normal"; that is, that they correspond to those of the average person.

benzoate, and wide differences exist in the ability to detect and recognize such odors as *verbena* and to distinguish between wines.⁷ R. J. Williams reports (*Science*, Dec. 11th, 1931) that a man whose sense of smell appeared otherwise normal could not detect the odor of a skunk, while *n*-butyl mercaptan, the "perfume" carried by skunks, had no unpleasant odor for him. Laselle and Williams^{7a} in attempting to identify a substance as creatinine, found it tasteless, though the literature states that creatinine is bitter. It was not until they had tried the sample on several others that they located someone who found it bitter. Since lean meat contains much creatinine (about 2 grams per pound), and soups made from lean meat contain extracted creatinine, we have another possible basis of differences in taste. Williams believes that the problem is associated with the more general one of individual metabolic idiosyncrasies, which crop up at times in medicine (*e.g.*, reactions to morphine, novocaine, iodoform) or in industry (reactions to cosmetics, "chemicals," etc.).

On the other hand the sense of smell of many animals is highly developed. Dogs follow a scent; deer, elk, and most wild animals can be approached only from the lee side. When offered a strange kitten, or sometimes even one of her own that has acquired a "foreign" odor, a mother-cat, after carefully sniffing it, will "spit" and box the kitten's ears to drive it off. Bees and ants are largely guided by odor, as are most insects in seeking food or mates. A Swiss scientist who had a female moth caged in his city laboratory far removed from parks or woodland, was astonished to see large numbers of males of the same species fly in. It has recently been shown⁸ that bats in flight emit sounds too shrill to be heard by the human ear but audible by bats, which even in pitch darkness are enabled to avoid objects (*e.g.*, the walls of caves) by sensing the reflected supersonic waves—an aural radar, so to speak.

Granting that we have come to an agreement as to the result of an observation, we have not reached an end but merely a new position from which to begin another advance. As Tennyson phrased it:

Yet all experience is an arch wherethro'
Gleams that untravell'd world, whose margin fades
For ever and for ever as I move.

Why is it that persons differ in their ability to taste phenylthiocarbamid? By what mechanism do extremely minute amounts of odoriferous substances enable cats and dogs, insects and wild animals, to draw such swift and certain conclusions? Is the so-called "sixth sense," commonly found in the blind and sometimes in the seeing, based on an unusually well developed sense of hearing, coupled perhaps with an extremely sensitive epicritic sense? Mice and bats ("flying mice") hear what to us is supersonic, and fish are believed to "feel" the presence of rocks by virtue of eddies or reflected waves of compression, not quite the same as "sound waves" in the water.

But it is not always easy to secure an agreement as to the "facts," especially if there is no obvious way of explaining a phenomenon on the basis of proven existing knowledge. A case in point is that of dowzers, who practice the art of locating underground streams of water. One branch of the divining-rod (a forked twig, usually of hazel) is held in the right fist with the clenched fingers up, the other branch being held in like manner in the left fist, with the forked center of the rod vertical. The dowser slowly walks across the area under investigation, and the fork is supposed to turn sharply downward when he passes over running water. Watching a successful dowser at work, I observed, as have others, that the downward turning of the fork is consequent upon a slight inward rotation of the clenched fists; and I found that this effect can be repeated voluntarily. When I traversed the same area as the dowser, the rod dipped in the same places as with him, and for the same reason—my wrists spontaneously turned inward. As a check, I had about ten persons, unacquainted with the dowser's findings, make the same experiment. Most of them got the same response as the dowser, with the same inward twist of the wrist.

On the other hand, dowsers tested in a laboratory with concealed pipes through which water could be made to flow at will, failed to locate flowing water; and many writers of repute consider the effect a conscious one, the dowser being a "good guesser," who depends upon observing types of vegetation, the lay of the land, etc. I am tempted to refer to this rather dangerous mooted question first, because it shows to what a remote level of material structure one may be forced to go in an attempt to explain a phenomenon, but especially because so eminent a scientist as Sir J. J. Thomson, Master of Trinity College, Cambridge, in discussing water-dowsing states:⁹

"There are some who can detect water without using the rod, since they experience peculiar sensations when they are in places where the rod would move. The rod may be a convenient indicator of a physiological effect. There is no doubt of the reality of the dowsing effect. In fact, in many agricultural districts the dowser is the man they call in when they want to find the right place to dig a well, and he very often succeeds. We had an example of this at Trinity College. The water supply to one of our farms was very defective and a new well was badly wanted. At first the Senior Bursar, who was a Fellow of the Royal Society, proceeded in the orthodox way and employed eminent geologists to report on where we ought to sink a well. Their advice, however, did not lead to the discovery of any water. Our land agent said, 'If I were you, I would try old X, who has found a good many wells in this county and who will sink the well on the terms 'no water, no pay.' As there seemed nothing else to be done, the Bursar employed him and he found water. For this we were assailed in an article in *Nature*, which lamented that Trinity College—the College of Newton—should have given countenance to such superstitious and unscientific practices.

"Although I think that most of the people who have paid any attention to the subject believe in the reality of dowsing, there is no agreement about its cause. . . . In some cases the movement of the rod occurs when the dowser has been blindfolded, or when he has not been near the part of the country before."

Thomson points out that all of the many English well waters he had examined contained radioactive emanation from radium which has a life of only four days, so that stagnant water would soon lose its radioactivity, and if this were connected with the effect on the dowser, it would explain why he can detect only *running* water.

Almost a century ago Quincke observed¹⁰ that when water is forced by pressure through a porous membrane or a single capillary, a potential difference is set up between the opposite sides of the membrane or the opposite ends of the capillary. This is known as "streaming potential." But I know of no evidence connecting the reactions of a dowser with any kind of electrical or other radiation, although something might be shown by refined apparatus similar to that used by Sir Edgar D. Adrian and his collaborators to measure the tiny and evanescent electrical impulses in single nerve fibrils,¹¹ and Loomis and Harvey¹² to record the Berger and other electrical rhythms of the brain. Thomson concludes:

"The divining-rod is perhaps, of all phenomena which may be thought to be psychical, the one most favorable for experiment. The motion of the rod is a mechanical effect and gives an indication of the magnitude of the phenomenon. The conditions under which the effect occurs can be made definite, and there is no lack of trustworthy people who possess the dowsing power: for these reasons I think such experiments are well worth making."*

* "Since the above was written I have seen a paper by Mr. H. M. Budgett, published by the British Society of Dowzers, on the connection between effects on a divining-rod and the readings of an instrument designed to detect very penetrating radiation. There seemed to be indications of some connection, but these were very faint. It would be interesting to see if the dowser could, by his divining, detect a strong beam of penetrating γ -rays." (Thomson). See also "Natural Potentials in Sedimentary Rocks" by P. A. Dickey, *Teel. Pub.* 1625, *Am. Inst. Min. and Met. Eng.*, (1943) J. A.

Most people do not think of "static" unless it affects radio reception; yet many fires and explosions * have been due to sparks developed upon the release of static charges arising from the friction of belts on pulleys, or of rubber tires on roads. Gasoline trucks have chains dangling in electrical contact with the earth, and at toll gates there are erect and grounded wires to carry off static charges which otherwise might give a sharp shock to both chauffeur and toll-taker. Modern printing presses have combs and other devices to "bleed off" frictional charges which would make the paper sheets unmanageable.

It might seem a far cry from sun spots to textile mill troubles; but a direct connection is claimed to be consequent upon electromagnetic disturbances set up by the spots in the earth's atmosphere,^{12a} for these accentuate conditions which usually do not seriously disturb textile operations. One mill had to close down some of its processes at times during a sun spot period, because excess static would not allow the fibers to draft properly. Trouble was widespread, and both machinery and fiber quality were blamed, although no change had been made in either. Static seems to be an important "imponderable," and it is not unlikely that atmospheric conditions suitable for textile operations depend largely upon the presence of sufficient ionization and moisture in the air to prevent troublesome accumulations of static. Under suitable atmospheric conditions combing the hair makes it "fly" or "bristle."

Tiny quantities of electricity may initiate extensive effects. Thus in the course of an informal discussion, Dr. Willis R. Whitney estimated that the energy utilized by a fly in crawling up one inch against the force of gravity (one "fly-inch" power), could, if released in Los Angeles, activate a radio aerial in New York for over thirty years. And even though Hamlet correctly observed that there are more things in heaven and earth than are dreamed of in our philosophy, when we try to explain a phenomenon we must not overlook principles of common knowledge, no matter to what structural level we may have to go.

The Application of Mathematics to Physical and Chemical Problems

The data obtained by experiment and observation are often subjected to what is termed rigid or rigorous mathematical analysis in order to develop the nature of the relations between individual observations and to deduce logical corollaries therefrom. A consideration of some of the principles underlying this highly valuable application of mathematics reveals certain pitfalls yawning for the unwary scientist who steps over into mathematics, as well as for the mathematician who deals with scientific data.

Pure mathematics deals with real and imaginary quantities and their relations, and is based on abstractions drawn from practical experience. Thus we know that two plus two make four, because if we have four apples and eat or give away two, we have two left. Certain primitive savages cannot count beyond one, so that when they trade sheep for knives, they place one knife with each sheep. The decimal system seems to have had its prehistoric origin in the fact that tally can be kept by the fingers. Eskimos describe *fifteen* as "two hands and one foot," and in keeping count it is usual to make four vertical strokes with a cross-stroke "tally" for five.

Pure mathematics has undergone great development, but has maintained its basic principle of dealing logically with abstractions which may or may not correspond to physical realities. Consider $\sqrt{-1}$, often used in electrical calculations. Untrammelled by material facts, a mathematician may romance like a novelist, providing only that he adheres to the logical use of assumed premises. And though life is often stranger than fiction, the mathematician Sylvester has said that a mathematician is never so happy as when he does not know what he is talking about.

* A press dispatch dated Nov. 10th, 1942, stated: "An explosion of anesthetic gas, reportedly caused by a static spark, killed a patient to-day as he was receiving a blood transfusion after a chest operation. . . ."

Applied mathematics, on the other hand, concerns itself with physical units and their behavior, and utilizes the logical, impersonal theorems of pure mathematics to express and develop qualitative and quantitative relations between these units and their behavior. Despite the great differences in philosophical and metaphysical theories and beliefs, and the admission that we cannot even conceive what are the ultimate units of matter, every person in his daily life shows by his actions that he believes matter to be *real*.¹³ The units of the applied mathematician may be electrons flying about atomic nuclei, or the levers of a machine, or the planets of the solar system; but whatever they are, the physicist and chemist are compelled to discover, by experiment and observation, certain facts and relations regarding them. It is usual to combine and reason mathematically with these findings, after expressing them in a condensed mathematical form, or *formula*. The word "formula" is a diminutive of the Latin *forma* (form), and therefore means simply "a little or concise form." The pure mathematician may assume facts to form a convenient equation, subject to mathematical manipulation. The applied mathematician, who is often a physicist or a chemist, must find equations to fit the facts, always remembering that equations are mute and make no protests against sins of commission or omission. St. Paul warned that we cannot be all things to all men; but a truly valid equation must be all things to all pertinent facts, known and unknown.

The history of science is full of instances where accepted notions have been discarded or modified because of new knowledge. Even in the days when diet was based on "fat, carbohydrate, protein, and total calories," any grandmother knew that cod-liver oil had a potency far greater than olive oil, its quondam theoretical dietary equivalent. The discovery of the importance of trace substances in the diet, including vitamins, iodine, copper, etc., and recognition of the fact that most proteins do not contain all of the amino acids essential to well-being, have led to a marked revision in feeding both humans and animals. Long before any scientific explanation was available for the use of protective colloids in modifying cows' milk for infant feeding, practical physicians had recommended and utilized the addition of gelatin, gum arabic, dextrinized starch and the like, and in folk practice such colloids as Irish moss, Iceland moss, and Bavarian beer (of high dextrin content) were used.¹⁴

Certain elements exist in allotropic forms that owe their differences to the way in which their constituent atoms are assembled. This raises the question as to the minimum number of atoms which must get together in a certain configuration to make the smallest conceivable particulate unit of a certain allotrope. Thus a single carbon atom can not be graphite or diamond. Theoretically, the smallest unit we could call graphite must have at least twelve carbon atoms, arranged in two hexagonal layers 3.40 Å apart, while in diamond we can imagine a minimum unit of five carbon atoms, four being arranged in the form of a regular tetrahedron whose side is 1.54 Å, with the fifth carbon atom centered within. Particles handled experimentally are usually very much larger than these suppositious minimum units, but rings of six carbon atoms have been demonstrated in the mass spectrograph. By electron diffraction methods Germer and White estimate that the smallest crystals formed by vaporizing copper on supporting foils of iron or of Invar gave ring intensities between those calculated for crystals of 55 and of 397 atoms each.¹⁵

In J. W. Mellor's monumental book,* Vol. V, p. 720 (1924), it is stated: "Boart and carbonado are usually regarded as forms intermediate between diamond and graphite." The following descriptions are condensed from the catalog of a large

* Mellor quotes Lucretius (60 B.C.): "It matters much with what others, and in what positions, the same atoms are held together. . . . When the configuration of the atoms is changed, the properties of the body which is formed from them must also change." H. A. Miers (article on "Diamond" in "Encyclopedia Britannica," 11th ed., 1910) stated: "Both boart and carbonado seem to be really aggregates of crystallized diamond, but the carbonado is so nearly structureless that it was till recently regarded as an amorphous modification of carbon."

dealer in industrial diamonds: *Boarts* (borts) are more or less transparent crystals of most varied shapes, sometimes twin and multiple formations. *Carbons* (carbonado), often called amorphous diamonds, differ essentially from boarts in structure; they are a porous cluster of minute diamond crystals, fine to close-grained. The fracture of a good carbon should resemble the structure of fine steel. Much harder than boarts, and much less fragile, they can be used until entirely consumed. *Ballas** are roundish aggregations of innumerable minute crystals grouped concentrically about a nucleus. Being non-porous and devoid of cleavage planes, they are about as hard as good carbons, but tougher because of their structure. Brazilian

FIGURE 1. X-ray spectrogram of poor quality carbonado (unfiltered Mo radiation; distance 5 cm) Courtesy G. L. Clark.

FIGURE 2. X-ray spectrogram of high quality carbonado (unfiltered Mo radiation; distance 5 cm) Courtesy G. L. Clark.

ballas is used to test the hardness of carbons. When the two are rubbed together, a white mark indicates that the carbon is harder, while a dark brown mark indicates that the ballas is harder. If both stones are of equal hardness, no mark results on either.

Early in 1928 I secured specimens of ballas, and of a fine and a poor grade of carbonado, and Professor George L. Clark kindly took x-ray spectrograms of them all. The results indicate that the ballas was composed of a great number of small diamond crystals, the poorer carbonado of still smaller and more numerous crystals, while the fine carbonado had still finer crystals, many being of colloidal dimensions so that the rings of its x-ray spectrogram were continuous. No other form of aggregation than that of diamond was apparent¹⁶ (See Figs. 1 and 2).

*The word "ballas" appears to be a modified form of the Portuguese word *balas*, meaning *bullets*. The Spanish and Portuguese word *bola* means *ball*, whence is derived the Argentine *bolas*, the throwing-rope having ends weighted with heavy balls. . . . Through the Latin *ballista*, the word goes back to the Greek *βαλλειν*, meaning to *throw*. *Palla* is an old German form; and the golden balls of the house of Medici, now used by pawn-brokers, were known as *pallé*, which was the rallying cry of the Medici retainers.

Currently Recognized Structural Units and Levels

It is not so long ago that students were taught that atoms represent the lower limit of material structure: curious sphere-like bodies, all alike for each element, having potent but inscrutable idiosyncrasies or "affinities." Prout's hypothesis (1815) that all elements are built up from some single basic unit ("protyle" or hydrogen) was considered as having been completely disproved by the meticulous atomic weight determinations of Stas. We now know that only in relatively few of the elements (*e.g.*, He, Na, P, V, Mn, Co, As, I, Au, Bi, among the commoner ones) are the atoms all alike, for most elements have a variety of *isotopes*—atoms closely alike in chemical behavior but different in mass.* Thus chlorine is a mixture of about 76 per cent of an isotope of mass 35, with 24 per cent of an isotope of mass 37; tin has ten isotopes varying in mass from 112 to 124, and lead seven with masses from 203 to 210. The careful atomic weight determinations of T. W. Richards and others have shown differences in the atomic weight of lead from several sources. Furthermore, though the structure of atoms is not as simple as Prout had assumed, the basic work of Lord Rutherford and many others has shown that all the diverse elemental atoms are built up of a few units which we are at present unable to resolve further.

Starting with these basic units as our present null point, there is given below a triplex table which aims to illustrate the currently recognized structural levels or orders of material complexity commonly found in nature. On the left appear the basic material units and unit structures generally recognized by physicists and chemists. In the middle, at corresponding levels, appear the units recognized by biologists, geneticists, and medical men; and on the right, units demonstrable in cotton textiles, in starch, and in steel. As we rise to the larger and larger aggregates, the definiteness and strength of the forces holding together their proximate sub-units diminishes, and the boundaries between structure levels become less definite.¹⁷

The table demonstrates *the great importance of structure*, for from comparatively simple chemical elements and molecules, diverse and complicated structures develop, whose properties are greatly influenced by the manner in which their sub-units are assembled and held together.¹⁸ It is impossible to do more than to suggest in the table the importance of secondary substances which, when present in sizable amounts or even in traces or as "impurities," may exercise an influence upon structure and function quite unexpected and out of proportion to the amount present.

Mixtures vs. Pure Substances

Mixtures often show curious properties. Thus "half and half" solder melts at 220° C, which is far below the melting points of its constituents, tin (m.p. 232° C) and lead (m.p. 327° C). The influence of colloids upon crystallization, long ago recognized,¹⁹ is of great biological and technical importance. The quantity needed to produce a marked effect may be very small. Thus .01 per cent gelatin greatly retards the setting of plaster of Paris and prevents the formation of the ordinary visible crystals. Minute quantities of protective colloids may cause precipitates to fall out in the colloidal state, and small amounts of "addition compounds" greatly affect the electro-deposition of metals.²⁰

H. G. Bungenberg de Jong and H. R. Kruyt³² found that when the dispersed substance in hydrophilic sols is thrown out by a variety of methods, *e.g.*, salts in large or in small amounts, removal of solubilizing salts, temperature change, addition of an oppositely charged sol, the "precipitate" often forms viscous droplets which aggregate into a fluid mass called a *coacervate*, instead of forming a solid phase. The phenomenon, termed *coacervation*, had been observed by F. W. Tiebackx,³³ who commented on the resemblance to casein of the gelatin-gum arabic coagula. Strongly adsorbed shells of water are supposed to surround the droplets and act as a protective

* See Appendix in this volume for table of natural and artificial isotopes of the elements.

Successive Levels of Material Structure

Elementary Particles (at present (1943) recognized)

| Order of Complexity 0 (?) | Charge | Size (Å) | Mass (gram) | Discoverer | Where Found |
|------------------------------|--------|--------------------|------------------------|---|--|
| Electron..... | -e | 3×10^{-5} | 9×10^{-28} | Sir J. J. Thomson (G. Johnstone Stoney) (Sir Wm. Crookes) | Electric current Negative electrostatic charges Nuclear satellites and emissions |

film along the lines suggested by Zsigmondy for the protective action of water.* In the case of many coacervates it seems likely that some impurity, or some fraction of one of the ingredients, may separate at the droplet interface and serve as a colloidal protector. It is well known that very pure materials, *e.g.*, iron, vanadium, may have properties quite different from even ordinary C.P. substances.

The effect of a product in a mixture varies with the specific natures of the substances mixed, or formed on mixing. Thus practical cooks use butter, hydrogenated oil, lard, etc., to make cakes and cookies "tender," and similar "shortening" materials are added to make pie crust "flaky." Such additions weaken the cohesiveness of the final product. On the other hand, technologists in various fields use small amounts of colloidal material to make the final product stronger; *e.g.*, rosin size in paper; starch size in warp yarns; thin layers of adhesives in building up cardboard and wood veneers. It often happens that thin layers of secondary materials become adsorbed at micellar surfaces, and act as *cohesive colloids*, binding the micellar or other small units into coherent structures.²¹ This may be the case with starches, where the binder, "amylopectin," appears to have the same ultimate chemical analysis as "amylose." About twenty years ago Sponsler²² showed that grinding destroys the x-ray pattern of starch which is due to some symmetry of structure in the granules; and recently Lampitt, Fuller and Goldenberg²³ ground starch for as long as 7,000 hours in a ball mill and concluded that grinding breaks the weaker lateral linkages without any significant breakdown in the "repeating units," identified by Brawn, Hirst and Young²⁴ as consisting of from 24 to 30 anhydro- β -glucose units. Glycogen ("animal starch") appears in similar "chains" composed of either 12 or 18 glucose units.²⁵ Farr²⁶ believes that ellipsoidal units of cellulose are cemented into fibrils by a cohesive substance which contains some pectin. Recently, Zweifach²⁷ stated that cells in the capillary wall are bound together by a calcium protein compound, and that diffusion takes place through this intracellular cement rather than through the cells themselves.

The Importance of Impurities

Although the importance of "impurities" has long been stressed, the mistaken popular notion still persists that an ordinary "chemical analysis" (usually presented in the form of atomic percentages) will tell all one needs to know about a manufactured or a natural product. The consulting chemist usually has to bring home the importance and delicacy of structure by pointing out, for example, that although dropping a watch on the floor may not change its chemical composition, the shock may ruin its value as a timepiece. Scientifically, recognition of the importance of structure has been a matter of gradual growth, mainly because scientists are prone to magnify and reason with the factor they can understand and explain, and fail to suspect that "rigorously exact" or "strictly quantitative" measurements may be vitiated, as von Weimarn emphasized,²⁸ by variations in structure and by the existence of unknown factors.

In plant and animal nutrition, nowadays, we hear much of secondary substances (*e.g.*, "roughage"), of impurities (*e.g.*, the average hen's egg contains about a milligram of zinc), and of trace substances essential to growth and life (*e.g.*, vitamins, copper, iodine, boron, etc.). Dr. R. A. Steinberg (U. S. Dept. of Agriculture, 1939) reported that a common mould needs traces of gallium to grow and reproduce—10 to 30 parts per billion of water are necessary, and no other element appears to serve as a substitute. In cases where such minute quantities are so potent, the presumption arises that the trace element enters into the formation of a catalyst.²⁹ Robinson, Whetstone and Scribner³⁰ investigated the abnormal behavior of alumina from leaves of a hickory tree growing in a Virginia pegamite vein, found that at least 0.2 per cent of the dry weight of the leaves consisted of rare-earth oxides.

* "Colloids and the Ultramicroscope," Chapter 18, translation by J. Alexander, New York, 1909.

mainly of cerium, lanthanum, praseodymium, neodymium, yttrium, samarium, and europium. Sir F. G. Banting³¹ in speaking of the purification of insulin, said: "With the elimination of impurities the insulin was more rapidly absorbed and the duration of its effect was lessened. . . . Hagedorn (of Denmark) and his colleagues, 1933-35, found that the addition of protamine to their insulin so delayed the action that the day's supply of insulin could be given in one injection. This was the greatest advance in the treatment of diabetes since the discovery of insulin. Scott (of Toronto) found that when protamine was added to zinc-free amorphous insulin, there was little or no delay in the rate of absorption. If, however, zinc was added, a combination occurred between the insulin and protamine with the characteristic slowing effect of the protamine. It would seem that the Danish insulin contained sufficient zinc or other specific metal to produce this combination." The effects of zinc-insulin (without protamine) seem to be intermediate between those of pure insulin and zinc-protamine-insulin.

For many years it had been taught as an elementary distinction that non-living things grow by *accretion*, whereas living things grow by *intussusception*. For example, Thomas Huxley stated in his "Anatomy of Invertebrates" [p. 10 (1888)]: "The increase in size, which constitutes growth, is the result of a process of molecular intussusception, and therefore differs altogether from the process of growth by accretion, which may be observed in crystals." But all growth is ultimately accretional, as was pointed out by J. Alexander and C. B. Bridges in Vol. II of this series, pp. 17-18. For on considering the table of material units, it at once becomes evident that intussusception in any unit of a higher order of complexity may be resolved into accretion at the surface of particles at some lower level; and conversely, accretion at the surface of particles grouped to form a unit of higher complexity results in the growth of this mass by intussusception.

Much of the "mystery of life" arose from inability to descend to levels of structure where basic life processes could be coupled up with chemical knowledge. Thus Goethe, himself a biologist, put the following words into the mouth of Mephistopheles (*Faust*, Part I, line 1581 ff):

Who would know and describe a living thing,
First kills it, the spirit severing;
The parts he holds, without a kink,
But lacks, alas, the spiritual link.
Encheiresin naturae says Chemistry now,
Mocking itself, for it knows not how.

And Alexander Pope wrote:

Like following life through creatures you dissect,
You lose it in the moment you detect.

Several papers in this volume show how clear a notion of physical life may be had at the catalytic level, in the colloidal zone.

In attempting to envisage the mechanism underlying a phenomenon, it is necessary to focus attention initially upon the structural level where the crucial factors are operative. Thus with radioactivity we consider the nuclear level; with chemical problems, the atomic and molecular levels. Structures of the most diverse chemical nature (iron, wood) may function as chairs, though tests may be devised to bring out the chemical differences. As a rule changes at lower levels exert potent influences at higher levels, and vice versa. Apparently conflicting observations may often be resolved when structural interrelations are properly appreciated and appraised.

13. There is a story that Bishop Berkeley saw one day the following limerick pinned on a tree in the University quadrangle:

A young Oxford man remarked: "God
Must think it exceedingly odd
That this sycamore tree
Continues to be
When there's no one about in the quad."

Next morning the philosopher's reply was found pinned below:

Dear Sir: Your bewilderment's odd:
I'm always about in the quad;
So this sycamore tree
Will continue to be
Since observed by, Yours faithfully, God.

The Surfaces of Solids and Liquids and the Films That Form upon Them

PART I. LIQUIDS

WILLIAM D. HARKINS

University of Chicago and the Universal Oil Products Company

Introduction: Surfaces and Interfaces

The surface of a solid or a liquid, or the interface between any two three-dimensional phases, is a region of discontinuity which is extremely thin, except at temperatures very close to the critical point. The discontinuity in the density of the material is a manifestation of the extremely rapid variation in the intensity and shape of the electric fields with the distance from the surface. If this is plane there is a dissymmetry of the field, with reference to the plane, which results in more or

less orientation of the molecules in the surface region. In the special case in which long, straight-chain organic molecules are tightly packed in an interface, they are in general oriented either perpendicular to or parallel to the surface.

The perpendicular orientation is discussed in Volume I of this series, and the parallel orientation in a later section. The idea of molecular orientation in surfaces

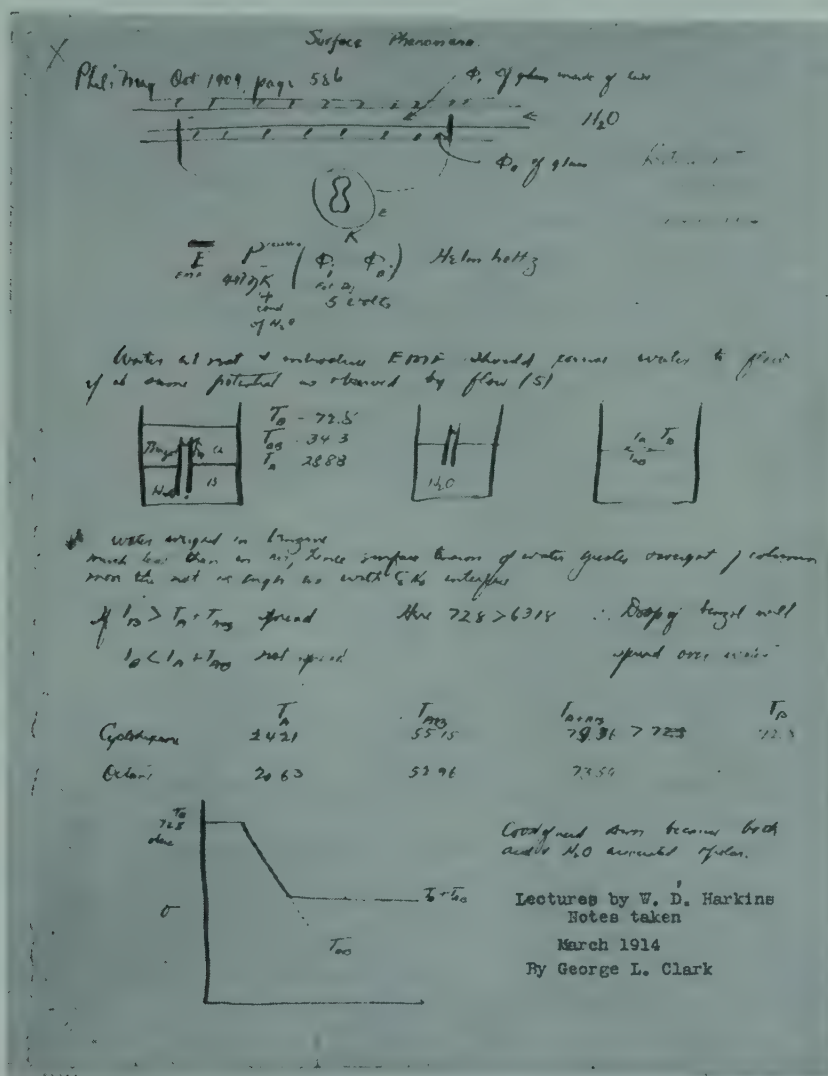

FIGURE 1. Earliest record of the direction of orientation of molecules at the surface of a liquid.

was developed independently by Sir William Hardy and by the writer, but the earliest series of lectures on this subject was presented by the writer at the University of Chicago in the winter of 1913-14. Since, however, Hardy did not give the direction of orientation of molecules in the surface, but merely indicated that the surface is a region of discontinuity, Fig. 1, a record of one of these lectures, is of considerable interest, since it indicates that polar groups orient themselves toward the water. This figure also represents a very early application of the idea of the spreading coefficient to show that benzene must spread on a clean water surface. It will be shown later that the denial of this fact has been made the basis of one of the most prominent theories of the spreading of films on water.

FILMS

Formation of Films

Films may form upon the surface of a liquid or a solid either by condensation from a vapor (adsorption) or by the spreading of material from a liquid or a solid body, which floats upon, or is in contact with, the surface. Films may also form by adsorption from a solution or by spreading at an interface, as, for example, between oil and water, between mercury and another liquid, or between a solid and a liquid. Thus either oleic or stearic acid spreads readily at an oil-water interface.

The type of film which spreads is determined by the interfacial free energy relations involved, as is shown later. Where the free surface energy would be decreased if a film of a certain type should spread, then it may spread; but if an increase of free energy is involved, it will not spread.

Three general types of films need to be considered:

- (1) Monolayers: one molecule thick.
- (2) Films thicker than monolayers, but thinner than duplex films.
- (3) Duplex films: the film is sufficiently thick to give complete independence between the energy of the surface and that of the interface.

The Spreading of Oil Films on Water ^{21, 35, 81, 83 *}

Oxidized Oils. If a drop of fresh Nujol, a heavy hydrocarbon oil, is put on a clean surface of water it does not spread, but remains as a thick lens. If the Nujol has been oxidized by air by stirring it in an evaporating dish over a flame, it is found to spread as a uniform polymolecular film over a considerable area. If, for example, the area of the surface of the water in a rectangular trough is 5×10^3 cm,² a small drop of this oil spreads over the surface to form an invisible film, which, on moderate decrease of area on compression by the use of a movable barrier, exhibits a uniform light yellow color in white light. On compression the color changes to dark yellow, gold, red, purple, blue, and green, and these colors then repeat themselves as the spectrum moves through four or more orders, but in the higher orders the colors red and green become much the most prominent. On further thickening, the film becomes colorless. An experiment such as this involves films of a uniform optical thickness between a few hundred and several thousand Angström units. The limits of thickness are much greater than this.

Such polymolecular liquid films may be designated as duplex, since their upper and lower surfaces are far enough apart to make their surface energies entirely independent of each other. Thus the total free energy, γ_d of unit area of the duplex film of a liquid *b* on a liquid *a* is given by the expression:

$$\gamma_d = \gamma_b + \gamma_{ab} \quad (1)$$

Such a duplex film is, in general, unstable. Thus an oil film on water which exhibits a single diffraction color is always found to segregate into regions of varied thickness, and therefore of varied colors, at the end of a period which varies from a few seconds to a few weeks. In order to understand what occurs, a knowledge of the thermodynamics of films is essential.

If a crystal of an organic acid, an alcohol, or an ester is placed on the surface of clean water, it is found to spread as a monolayer. Oleic acid seems to spread to some extent as a duplex film, but the monolayer spreads more rapidly and therefore ahead of the duplex film, which changes rapidly to a monolayer and lenses.

Theories of Spreading. There are two *special* theories of the spreading of oil on water.

* A considerable part of the discussion of spreading, and of the tables of this chapter, have been taken from a paper by the writer in *Chemical Reviews* 29, 385-417 (1941) by permission of W. A. Noyes, Jr., editor, and of Williams and Wilkins, publishers.

(1) Rayleigh's theory:^{a,b,c,d} All liquids spread on the surface of clean water. To prevent spreading, it is necessary to have a foreign substance on the surface.

(2) Langmuir's theory:^{e,f} Non-polar liquids, such as the hydrocarbons, do not spread on water, but if the molecules contain a polar group and a non-polar group, the liquid will spread.

It is obvious that these two theories are in disagreement, so both cannot be true. Rayleigh's theory is in a certain sense correct, namely to the same extent that all liquids and solids are volatile. The error in Langmuir's theory is that while polar groups aid in spreading on water, the process occurs with many oils which contain no polar groups; or may not occur if a polar group is present, provided the non-polar part of the molecule is sufficiently large.

In addition there is a single general theory of spreading as outlined below.

(3) The general thermodynamic theory of Harkins,⁸⁹ which is not limited, but applies to all liquids, to the spreading of solids on liquids, and to the spreading of mobile films on solids. The theory is based on the concept that there are two types of spreading:^{*} (a) Duplex (D) spreading: a liquid, such as benzene or the oxidized Nujol already considered, may spread as a duplex film. The thermodynamic relations indicate that this is unstable and always transforms into a non-duplex film (a monolayer) and a lens or lenses. (b) Non-duplex (or M) spreading: a non-duplex film may spread directly from a three-dimensional solid or liquid, or it may be formed by the transformation of a duplex film. All non-duplex films of known thickness are monolayers.

Duplex spreading: The theory of the spreading of a duplex film may be stated in the following abbreviated form: If a drop of an insoluble oil (*b*) is placed on a clean water (*a*) surface, it may or may not spread. The condition which determines whether or not the oil spreads is exceedingly simple. If the oil likes itself (W_{cb}) better than water (W_a) it will not spread, while if it likes the water better than itself, it will spread. In order to use this relation in a quantitative sense it is essential to express the term "likes" as a thermodynamic quantity, which is done in the following equation:

$$S_{b/a} = -(\partial F / \partial \sigma)_{p,T} = W_A - W_{cb} \quad (2)$$

Here $-(\partial F / \partial \sigma)_{p,T}$ is the rate of decrease of the free energy (F) of the system with increase of area (σ) of the duplex film, and the concomitant decrease in the area of the clean surface of the water. W_a is the work required to pull the oil and water apart over an area of 1 sq cm, and W_{cb} is that required to rupture a bar of oil with a cross-section of 1 sq cm of surface of the oil (Figs. 2 and 3). A consideration of these processes gives values for W_a and W_{cb} as follows:

$$W_A = \gamma_a + \gamma_b - \gamma_{ab} \quad (\text{Dupr\'e's equation}) \quad (3)$$

$$W_{cb} = 2\gamma_b \quad (4)$$

so

$$S_{b/a} = \gamma_a - (\gamma_b + \gamma_{ab}) \quad (5)$$

Benzene. In order to obtain a better idea of the extent to which each of the three theories is valid, the discussion given below considers the spreading of three liquids—benzene, carbon disulfide, and a paraffin oil of high molecular weight.

^{*} Hardy also assumed two types of spreading: primary, which corresponds to non-duplex, and secondary, which corresponds to duplex. One of the principal differences is that Hardy assumed non-duplex films to be moderately thick, while here they are assumed to be monomolecular in general.

For dry benzene on a clean water surface, what may be termed the initial spreading coefficient has the value

$$S_{b/a} = \gamma_a - (\gamma_b + \gamma_{ab}) = 72.8 - (28.9 + 35.0) = 8.9 \text{ ergs cm}^2 \quad (5)$$

That is, if the area of the duplex film increases by 1 cm^2 and that of the clean surface of the water decreases by this amount, there is a decrease in free energy of 8.9

FIGURE 2. (A) If the liquid b is pulled from the liquid a at the plane p , the increase in free energy is $\gamma_a + \gamma_b$ in the ideal case in which the liquids are completely separated from each other. There is a concomitant decrease of free energy equal to γ_{ab} , due to the destruction of the interface of ab . The work done (W_A) equals the net increase in free energy, or $W_A = \gamma_a + \gamma_b - \gamma_{ab}$. (B) If the liquid b is pulled apart at the plane p , the increase in free energy is $2\gamma_b$, or $W_{cb} = 2\gamma_b$.

FIGURE 3. Idealized diagram illustrating the separation of a bar of liquid alcohol into two parts. The molecules are represented as already oriented at the interface, since the break is well under way. This diagram indicates that in such an ideal case the energy of separation of a moderately long-chain alcohol should be practically equal to that of a hydrocarbon of the same molecular size, except for the relatively small energy of orientation of the molecules at the interface before the actual separation has occurred.

ergs, which is a considerable one; and this indicates that benzene should spread readily to form a duplex film.

However, since the extremely thin duplex film of benzene becomes saturated with water very rapidly, the coefficient of spreading changes rapidly to the semi-initial coefficient, which is

$$S'_{b/a} = \gamma_a - (\gamma'_b + \gamma_{a'b'}) = 72.8 - (28.8 + 35.0) = 9.0 \text{ ergs cm}^{-2} \quad (6)$$

where the prime indicates that b is saturated with a . The value of this spreading coefficient indicates that wet benzene also spreads on a clean water surface to form a duplex film.

If b and a are mutually saturated, then

$$S_{b'/a'} = \gamma_a' - (\gamma_b' + \gamma_{a'b'}) = 62.2 - (28.8 + 35.0) = -1.6 \text{ ergs cm}^{-2} \quad (7)$$

This may be designated as the final spreading coefficient. Its negative value indicates that benzene will not spread over the surface of water if the liquids are mutually saturated. An inspection of the numerical terms involved shows that the whole change between $S_{b'/a}$ and $S_{b'/a'}$ is due to a decrease of $10.6 \text{ ergs cm}^{-2}$ in the free surface energy of the surface of water. Now if the free surface energy of the water saturated with benzene is subtracted from that of the clean water, there is obtained as the difference (π_e)

$$\gamma_w - \gamma_e = \pi_e \quad (8)$$

where, if surface tensions instead of free surface energies are considered, π_e is by definition the film pressure, and the subscript in γ_e indicates that the film of the oil b is in equilibrium with a lens of the oil.

Now equation (6) minus equation (7) gives

$$S_{b'/a} - S_{b'/a'} = \gamma_a - \gamma_a' = \gamma_w - \gamma_e = \pi_e \quad (9)$$

or the difference between the semi-initial and the final coefficients of spreading is equal to the equilibrium film pressure. It is shown above that for benzene on water this difference is $10.6 \text{ ergs cm}^{-2}$, which is therefore the value of the film pressure of the non-duplex film of benzene on the water.

To obtain this thin film a clean surface of water in a large crystallizing dish may be partly covered with a layer, that is, a large lens, of benzene. If the curvature of the surface of the water is adjusted to give such a result, the lens or layer (*ca.* 2 mm thick) will form an annular ring in contact with the outer edge of the dish, while in the center a circular hole will be formed. According to Langmuir, there is no benzene film in this hole, but the vertical type of film balance, or the ring method, may be used to test this, and such a measurement gives a film pressure of $10.6 \text{ dynes cm}^{-1}$. Thus the surface of the water in the hole is covered with a monolayer which gives this high pressure, corresponding to about 200 atmospheres. Obviously this monolayer is in equilibrium with the large lens.

Carbon Disulfide. (Fig. 4). For carbon disulfide on water the semi-initial coefficient of spreading is

$$S_{b'/a} = \gamma_w - (\gamma_o' + \gamma_{wo}') = 72.8 - (31.8 + 48.6) = -7.6 \text{ ergs cm}^{-2}$$

and the final coefficient is

$$S_{b'/a'} = 70.5 - (31.8 + 48.6) = -9.9 \text{ ergs cm}^{-2}$$

or

$$\pi_e = S_{b'/a} - S_{b'/a'} = 2.3 \text{ ergs cm}^{-1}$$

Thus the values of the initial and semi-initial spreading coefficients predict that carbon disulfide will not spread as a duplex film; but the difference between the semi-initial and final spreading coefficients indicates that it does spread as a monolayer, which has an equilibrium film pressure of $2.3 \text{ dynes cm}^{-1}$. Presumably this monolayer is a gaseous film. Obviously it may have any film pressure less than $2.3 \text{ dynes cm}^{-1}$ if it is not in equilibrium with a lens of the liquid and the vapor from the liquid.

Methylene iodide, a non-spreading oil in the sense that its spreading coefficient has a very large negative value ($S_{o'/w} = -23.6$ and $S_{o'/w'} = -24.2$), nevertheless gives a non-duplex film or monolayer with a film pressure of $0.55 \text{ dyne cm}^{-1}$.

Paraffin Oil of Very High Molecular Weight. A paraffin oil may have a molecular weight so high that at 20°C it gives almost no vapor pressure in three di-

mensions. Such an oil gives a high negative spreading coefficient, so it does not spread as a duplex film. Its cohesion is so large that it does not even spread as a gaseous monolayer, at least not sufficiently to give a measureable film pressure with the ordinary type of film balance. Such an oil may be considered as non-spreading.

Normal hexadecane (M. W. = 226) has an initial spreading coefficient of -9.31 , so it does not spread as a duplex of film. The equilibrium pressure of its gaseous monolayer has not been determined, but is presumably small.

Free Energy Diagram for the Spreading of Oils on Water (Fig. 4)

The amount of work involved in forming one sq cm of a clean, plane surface of water at 20°C is 72.8 ergs. Thus in a diagram (Fig. 4) the surface of water may be considered as existing at a free energy level of 72.8 erg cm^{-2} . Any oil which can reduce this free-energy level by spreading to give any particular type of film may spread to give such a film. If the particular type of oil film lies at a higher free-energy level than that of water, it will not spread spontaneously, and if it could be spread by any mechanical means, would be unstable.

It is apparent from the figure that all four of the liquids represented spread on water to form monolayers. The spreading coefficient, that is the decrease in free energy involved when a lens of the oil spreads to form its equilibrium monolayer, is given by the value of the film pressure, π . The values in erg cm^{-2} are as follows: *n*-heptyl alcohol, 44.2 ; benzene, 10.7 ; carbon disulfide, 2.3 , and methylene iodide, 0.6 . Thus this diagram appears to justify that part of Rayleigh's theory which considers that all liquids spread on water. However, the equilibrium film pressure of a non-polar liquid oil of very high boiling point, such as octadecane, is presumably very low (at 30°C). The film pressure of a solid *n*-paraffin of very high molecular weight is extremely small and would be difficult to detect.

With respect to their spreading as duplex films all liquids fall into two classes: those for which the free energy of the duplex film is (1) below, and those for which it is (2) above, that of the subphase. The free-energy level of any duplex film is equal to the sum of its two interfacial energies, or $f = \gamma_o + \gamma_{ow}$. Thus for benzene, saturated with water, $f = 28.8 + 35.0 = 63.8$, while for dry benzene $f = 28.9 + 35.0 = 63.9$. Thus the duplex film does not exhibit a single free-energy level, but its different levels are close together.

The decrease of free energy for the spreading of a duplex film of benzene on water is 9.0 erg cm^{-2} , and for isopentane 9.4 erg cm^{-2} , which indicates that not only aromatic compounds, but also lower *n*-paraffin oils, spread readily on water to form duplex films.

While carbon disulfide and methylene iodide spread as monolayers, it is evident that they do not form duplex films.

The lower hydrocarbons are found to spread both as duplex films and monolayers, and those of higher (but not too high) molecular weight give monolayers alone.

The Non-Spreading of Water on Organic Liquids

From the relation for the initial spreading coefficient

$$S_{b/a} = W_A - W_{Cb} = \gamma_a - (\gamma_b + \gamma_{a'b'})$$

it has been found that water will not spread on the organic liquids for which the relations are known; presumably this means that it will not spread on any organic liquid. Here *a* is an oil and *b* is water. For isopentane, $S_{w/o} = 13.7 - (72.8 + 49.6) = -108.7$, an extremely large negative value. For carbon disulfide $S_{w/o} = 31.4 - (72.8 + 48.6) = -90$. For water on primary isoamyl alcohol, $S_{b/a} = 23.7 - (72.8 + 5.0) = -54.1$. However the greater mutual solubility of a pair of liquids such as these reduces greatly the value of the final spreading coefficient. Thus for

FIGURE 4. Free surface energy (f) diagram for the spreading of duplex films and of monolayers on the surface of water. The free surface energy of a duplex film is the sum of that for the interface (γ_{wo}) and for the surface of the oil ($f_a = \gamma_{wo} + \gamma_o$). The lower of the two energy levels of a duplex film represents oil saturated with water, while the upper level is that when no water is in the surface of the oil. S designates the semi-initial spreading coefficient $S_{b'ia}$, which may be positive (arrow pointing downward) or negative (arrow pointing upward). S' , which represents the final coefficient ($S_{b'ia}'$) is always negative. Obviously if the free energy of a duplex film is above that of water, it will not form; if below that of water it may spread, but is always unstable with reference to the formation of a monolayer (and a lens). For the spreading of water on an oil, the free-energy levels for the duplex film are above that for water (usually by 40 to 110 erg cm⁻²), so water does not spread on an oil as a duplex film. Thus, except for the greater height of the duplex level the diagram is like that for methylene iodide.

Any film the free-energy level of which is above that of water (72.8 ergs cm⁻² at 20° C) cannot spread, and any film the level of which is below that of water may spread spontaneously on water. Benzene, a non-polar liquid (isopentane has practically the same levels), should, according to the diagram, be able to spread either as a duplex film or as a monolayer, but only the latter is stable. For carbon disulfide, a non-polar liquid, the duplex film is at a free-energy level 7.6 ergs cm⁻² higher than that of a clean water surface, so a duplex film is not formed by spreading. The free-energy level of the gaseous monolayer is, however, 2.3 erg cm⁻² below that of the water surface, which rapidly attains equilibrium with the lens and the vapor in a saturated atmosphere.

this alcohol $S_b/a' = 23.6 - (25.9 + 5.0) = -7.3$, which, while still negative, is very small for water on an oil. However, it is obvious that the smallness of this value is due to the great reduction of the free surface energy of the water which is caused by the oil.

The Spreading of Liquids and Solids on Mercury (Fig. 5)

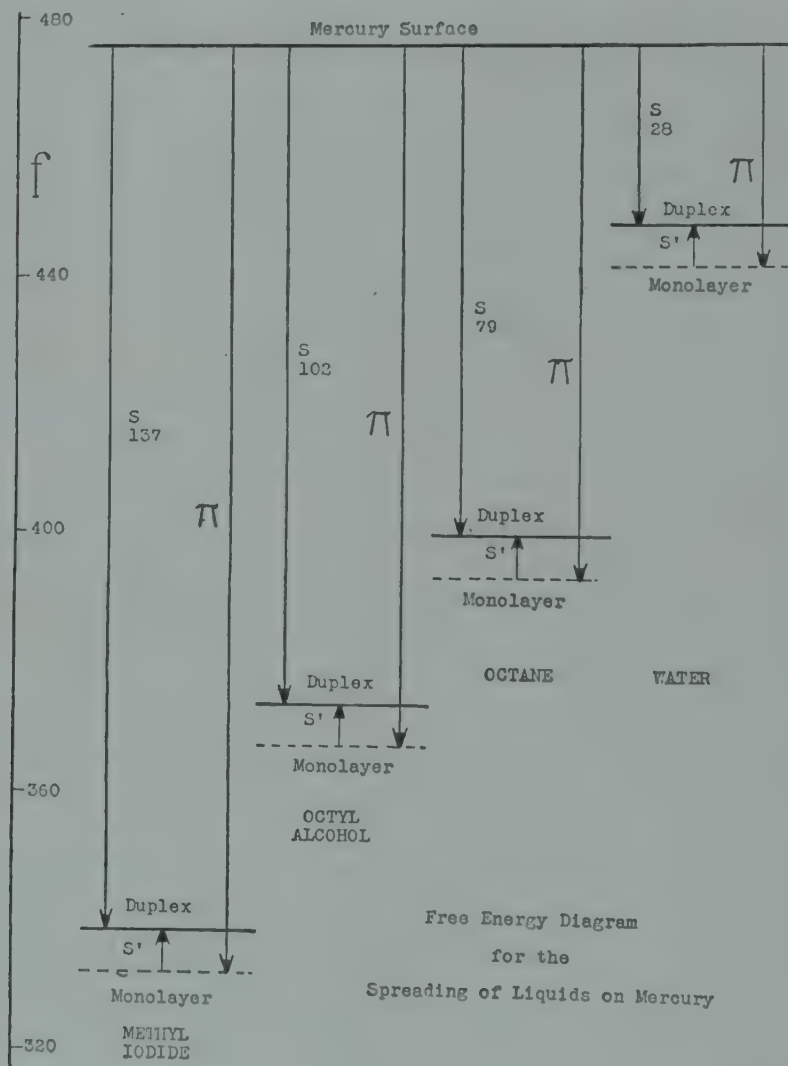

FIGURE 5. Water and all organic liquids have positive initial spreading coefficients on mercury, and thus may spread to form duplex films. The monolayers lie at a lower free energy level, so the duplex film, if formed, transforms into a monolayer and a lens. The free energy levels of the duplex films are known and are properly placed in the diagram. Those for the monolayers have not been determined, so only the sign of the final spreading coefficient (S') is known. While the film pressure is larger than the initial spreading coefficient, it is probable that it is not very much larger, so the diagram gives the general location of the free-energy level for each monolayer.

The free surface energy of mercury in erg cm^{-2} is: 480 at 0°C , 476 at 20°C , and 467 at 60°C . The total surface energy (h or c) is 540. Thus if a free-energy diagram, similar to Fig. 1, is constructed for the spreading of liquids or solids on

mercury, Fig. 5 is obtained and the level for the mercury surface at 20° C is very high (476). The result of this is that all duplex and all monolayer levels for water and for oils lie far below the mercury level. There is a large decrease in free energy if water or any liquid oil spreads as a duplex film on mercury. Thus water and all organic liquids spread on mercury.

There are no reliable determinations of the final spreading coefficient, $S_{b/a}'$, or of the equilibrium film pressure for any liquid on mercury. However, the lenses which form on the non-duplex film, presumably a monolayer, indicate that this film pressure is somewhat greater than the initial spreading coefficient, $S_{b/a}$. In ergs per cm⁻² the latter quantity has the values: water, 32; acetone, 60; hexane, 79; propyl alcohol, 85; carbon tetrachloride, 93; benzene, 90; chloroform, 97; octyl alcohol, 102; ethylene bromide, 116; ethyl iodide, 135; and methyl iodide, 137.

Many organic solids are found to spread on the clean surface of mercury.

Transformation of a Duplex Film into a Monolayer and a Lens

The examples given in this section show that in each case the free surface energy of the monolayer is less than that of the duplex film, provided the latter can spread at all. This is a general relation; the duplex film always changes into a monolayer and a lens (or lenses if the time is not sufficiently long to give a single lens). If a duplex film cannot form, any film that is produced is a monolayer. Such a monolayer may be formed even if the initial spreading coefficient is negative, but may not give a measurable film pressure if the oil is non-polar and does not give a measurable three-dimensional vapor pressure.

If the atmosphere above an oil film is supersaturated with oil, the material condensed on the monolayer does not thicken it; but any excess deposited on the monolayer either evaporates or goes into the monolayer. As a result of the latter process, either the monolayer expands, or an equal amount of material in the monolayer is forced into the lens.

The rate of spreading of an oil on water increases with the magnitude of the spreading coefficient and with a decrease in the viscosity of the layer which spreads. The values of the initial spreading coefficients of a few oils are given in Table 1. As the final spreading coefficient of an oil on water is always negative (Table 2),

Table 1

Reference 35, p. 25 (1928).

no oil will spread over its equilibrium monolayer. As the initial and final coefficients for water on oil are always negative, water will not spread over the surface of an oil.

Since (1) many hydrocarbon oils, which do not contain polar groups, nevertheless spread on water to duplex films and then to monolayers, and (2) substances whose molecules contain a strongly polar group do not spread if the hydrocarbon fraction is too large, it is apparent that the presence or absence of a polar group is not the true criterion for spreading or non-spreading. Examples of the second type are arachidic acid (20 carbon atoms) and acids having longer normal paraffin chains. These substances are solids because of the higher cohesion due to the longer chains.

Table 3. Effect of Molecular Constitution upon the Formation of Duplex Films and of Monolayers

| Molecules or Groups | Attraction for Water W_A | Attraction for Like Molecules W_C | Duplex Film ¹ | Stability of Monolayer |
|--|--|--|--|--|
| Hydrocarbons of high molecular weight -CH ₂ I, -CH ₂ Br, -CH ₂ I | Weak 60 Moderately strong 75 | Weak 65 Strong 100 | None None | None or gaseous None or gaseous |
| Hydrocarbons of low molecular weight Esters | Weak 45 Strong 80 Very strong 100 | Weak 40 Weak 50 Weak 50 | Unstable Unstable Unstable | Gaseous Stable. Relatively high compressibility Stable liquid, solid and gaseous |
| -CH ₂ OH, -COOH, -CN, -CONH ₂ , -C ₆ H ₄ OH, -NHCONH ₂ , etc. -SO ₃ H, -C ₆ H ₄ SO ₃ H, -SO ₄ H | Extremely strong Extremely strong | Moderately weak Moderately weak | Forms if material liquid, but unstable None | Form monolayers Form monolayers |

¹ If the spreading material is a solid, a duplex film does not form, but only a monolayer spreads. See Section 12 for the spreading of a duplex film of an oil which, of itself, does not spread in this way, by the addition of a polar-non-polar oil as a second component.

Table 3 expresses extremely general relations of the process of spreading, but it should be remembered that these cannot be entirely accurate.

PHASE RELATIONS OF MONOLAYERS

General Relations and Order of a Phase Transition

Monolayers exhibit surface phases in many respects analogous to those found in three-dimensional systems: (1) gas, (2) liquid, and (3) solid. There are in addition three other phases which seem to show no direct analogy to three-dimensional

systems. The first of these, discovered by Labrouste, is a coherent phase, and in that sense analogous to a liquid, but it may occupy as much as two and a half times the area of the most tightly packed liquid phase. In three dimensions this would be as if a quart of milk could exist in another expanded liquid state to give a volume as large as four quarts. This two-dimensional phase has been designated by Adam as an *expanded liquid* film.

There is also a phase of very high compressibility, with an area between that of the condensed and the expanded liquid phases, designated by the writer as the *intermediate* liquid phase. Some workers believe this to consist of small islands of the condensed liquid phase in a sea of the expanded liquid.

A sixth phase, discovered recently by Harkins and Copeland,^{87, 88} exhibits remarkable and anomalous properties. It has the small compressibility of a solid or *S* phase, but at certain temperatures is much less viscous than the condensed liquid (L_c) phase from which it is formed by increase of pressure. Since it shows some properties characteristic of the liquid, and others of the solid state it has been designated by the writer as the *LS* phase.

Since, also, the "solid," which is the most highly condensed phase, *may*, under some conditions, have a viscosity as low as that of a liquid monolayer and may exhibit no rigidity, it will be designated merely as the *S* phase.

Table 4. Two-dimensional Phases and Probable Order of Changes Between Them

| Phases | Order of Change Between Them |
|--|--|
| I. Gas, G . Includes compressed vapors such as the "vapor expanded" film of Adam Perfect gas: $\pi\sigma = kT$ Imperfect gas: minimum value of κ of same order as for L_1 films: e.g., 0.04 for ethyl palmitate at 25 C, 34\AA^2 , and 14 dynes cm^{-1} | I and II: first (L_1G) |
| II. Liquid, L_e (BC). "Liquid expanded" of Adam. Liquid of high compressibility $\kappa = 2 \text{ to } 7 \times 10^{-2}$ $h_s = 50 \text{ ergs cm}^{-2}$ | II (or I) and III: second (C) |
| III. Intermediate (I) or transition (CE). Liquid of extremely high compressibility Intermediate, I . Maximum κ of order of $2 \text{ to } 5 \times 10^{-1}$ for normal long-chain acids 2.2×10^{-1} for normal long-chain esters Minimum same as κ of L_2 film: $h_s = 300 \text{ ergs cm}^{-2}$, which is nearly constant at the higher areas, but decrease rapidly to a low value as transition to next phase is approached | III and IV: third (D) |
| IV. Liquid, L_c (DE). "Liquid condensed" of Adam. Liquid of low compressibility $\kappa = 5 \text{ to } 10 \times 10^{-3}$ $\pi = b - a\sigma$ $\log \eta = \log \eta_0 + k\pi$; h_s small | IV and V: first (perhaps anomalous) changing to second at higher temperatures. (See Fig. 14) |
| V. LS . Superliquid phase of extremely low compressibility $\kappa = 0.0005 \text{ to } 0.0017$. Viscosity becomes high at temperatures far above that of first-order change $\pi = b - a\sigma$ | IV and VI: second V and VI: second |
| VI. S . Previously classed as solid, may have the rigidity of a solid, or a non-Newtonian or a Newtonian viscosity. The most highly compressed phase. $\kappa = 0.0005 \text{ to } 0.001$ $\pi = b - a\sigma$ | |

These phases and their most prominent characteristics are outlined in Table 4, while their general pressure (π)-area (σ) relationships are represented in Fig. 6. No distinction is made in the figure between S and LS films, since it is on too small

FIGURE 6. General phase diagram of a monolayer at a temperature below the critical temperature for the formation of a liquid expanded (L_e) film. Phases: FE or S , solid: ED or L_e liquid condensed; DC or I , intermediate; CB or L_e , liquid expanded; BA or L_eG , gaseous film and L_e film in equilibrium; G gaseous film. The temperatures given are those for pentadecylic acid. For longer chain acids and for an alcohol of the same chain length the temperatures are higher, etc. The scale of molecular areas is much shortened (above about 47 Å) and the pressure scale is much expanded.

a scale for this purpose; but these highly condensed monolayers are shown later in Fig. 14.

The temperatures given in Fig. 6 are correct for pentadecylic acid, but are lower for acids with a lower, and higher for acids of a higher chain length. With alcohols the temperatures are much higher.

If a three-dimensional solid is changed to the liquid state, heat is absorbed by the system, and it seems difficult to conceive of the melting of a solid without the accompaniment of a latent heat. Such a phase transition is said to be a first-order change.

A phase change is of the second order, in the terminology of Ehrenfest, if latent heat is absent, and there are discontinuities in the heat capacity and in the coefficients of thermal expansion and compressibility. In a third-order change there is a discontinuity only in the derivative of the specific heat.

The order of a phase change is determined, according to Ehrenfest, by the lowest derivative of the free energy of the system which exhibits a discontinuity. As applied to monolayers this is indicated by the equations given below.

The Gibbs free energy is defined as follows:

$$F = E - ST - pv - \gamma\sigma \quad (10)$$

$$dF = dE - SdT - TdS - pdv - vdp - \gamma d\sigma - \sigma d\gamma \quad (11)$$

The differential of the internal energy (dE) is

$$dE = dQ - dW = T dS - p dv + \gamma d\sigma \quad (12)$$

so

$$dF = -S dT + v dp - \sigma d\gamma \quad (13)$$

and

$$(\partial F / \partial \gamma)_{p,T} = -\sigma \quad (14)$$

or, since

$$d\pi = -d\gamma \quad (15)$$

$$(\partial F / \partial \pi)_{p,T} = \sigma \quad (16)$$

$$(\partial F / \partial T)_{p,\sigma} = -s = -q/T \quad (17)$$

Thus a discontinuity in area at constant film pressure and temperature, or in entropy or heat absorbed, is a first-order change.

Now

$$(\partial^2 F / \partial \pi^2)_{p,T} = (\partial \sigma / \partial \pi)_{p,T} \quad (18)$$

$$\kappa = -\frac{\partial \sigma}{\sigma \partial \pi} \quad (19)$$

so a discontinuity in the compressibility without one in the area indicates a second-order change

Also

$$(\partial^2 F / \partial T^2)_{p,\pi} = C_\pi / T \quad (20)$$

$$(\partial^3 F / \partial \pi^3)_{p,T} = (\partial^2 \sigma / \partial \pi^2)_{p,T} \quad (21)$$

$$(\partial^3 F / \partial T^3)_{p,\pi} = \left[\frac{\partial (C_\pi / T)}{\partial T} \right]_{p,\pi} \quad (22)$$

and a discontinuity in the third derivative but not in the second, indicates a third-order change.

Gaseous or Vapor Films (G, Fig. 7)

FIGURE 7. General phase diagram at temperatures above T_c for the liquid expanded phase: ethylesters at 25°C .

At very large molecular areas of the order $50,000 \text{ \AA}^2$ the monolayer of penta-decylic acid seems to exhibit a behavior in accord with the perfect gas law $\pi\sigma = kT$, where σ is the molecular area and k is the Boltzmann constant of a three-dimensional gas. As the area is decreased, the two-dimensional gas becomes imperfect and the pressure increases in accord with a relation of the van der Waals type. If the temperature is 14.5°C the pressure becomes constant at a pressure of $0.11 \text{ dyne cm}^{-2}$ at an area of about $2,400 \text{ \AA}^2$ per molecule and remains constant until this is reduced to a relatively small area, above which the pressure increases. At 18°C this lower limit is 44 \AA^2 per molecule, but at 14.5°C it is probably about 26 \AA^2 . Between these limits the film is heterogeneous, and at temperatures about 19 to 40°C and more, consists of islands of expanded liquid film in a sea of gaseous film.

The heterogeneity of this film in the region L_1G of Fig. 6 has been demonstrated in the work of several investigators by a method suggested by the writer. This consists in surveying the surface of the film by moving over it an electrode with which the surface potential may be determined. If the film is entirely gaseous, the surface potential is in general less than 5 mv ; however, if there are islands or continents of a more condensed film this potential is much higher, since it increases in general with the mean number of film molecules under unit area of the surface of the electrode. The results of such a survey, as made by Harkins and Fischer, are shown later in Fig. 22. Here the maximum surface potential for myristic acid is at 56.5 \AA^2 , since the islands consist of patches of liquid-expanded film.

Compressed or High-pressure Vapor Films (Figs. 7 and 8)

FIGURE 8. Esters at 15°C .

If the temperature is above the critical point for the formation of a liquid-expanded monolayers, the vapor film may be compressed to relatively low areas and high pressures, as shown in Figs. 7 and 8, where the righthand, nearly hyperbolic curve represents a gaseous film. Such films have been designated by Adam as *vapor-expanded*, since their π - σ curves resemble those of "liquid-expanded" monolayers. They are distinguished from these by the fact that they exhibit higher pressures at large areas, and no discontinuity on further expansion, while such liquid-expanded films as have been investigated show a discontinuity at a molecular area of from 40 to 50 \AA^2 for single-chain molecules.

Compressed vapor films condense directly into the intermediate liquid state by a phase transformation of the second kind, that is without any latent heat of condensation. These relations show that a two-dimensional gas may condense into a liquid by:

- (1) A change of the first order with emission of heat.
- (2) A change of the second order without latent heat.

The Expanded Liquid Phase

The expanded liquid phase of a monolayer exhibits very nearly, but not quite, a hyperbolic relation between pressure (π) and area (σ), as shown in the curves on the right of Figs. 9, 10, 11 and 12, which represent the normal straight-chain paraffin

FIGURE 9. Liquid monolayers of myristic acid. Curve 7 for 25° C is shifted toward lower areas by the solubility of the film at this temperature.

acids of from 14 to 16 carbon atoms per molecule, and also octadecane nitrile. It is apparent that the areas of these hyperbolas lie at molecular areas above zero, and at film pressures below zero.

Langmuir has expressed this relation by the equation

$$(\pi + a)(\sigma - b) = nkT \quad (23)$$

but it is found that neither a nor b is a constant.

The Intermediate Liquid Phase. (Figs. 9, 10, 11 and 12)

On increase of pressure at constant temperature, decrease of area at constant pressure, or decrease of pressure at constant area, the expanded liquid phase is changed, by a transformation which seems to be of the second order, into the intermediate liquid phase.

The principal characteristic of this phase is its extremely high compressibility ($-\chi$), especially at its higher areas. This is so high that the transition considered above is sometimes considered to be of the first order. However the maximum com-

FIGURE 10. Liquid monolayers of pentadecylic (15-carbon) acid. The arrows indicate collapse.

FIGURE 10a. Phase diagram showing the regions of stability for the liquid expanded films of the fatty acids C_{13} to C_{16} .

compressibility of this phase varies widely with the type of molecule. For octadecane nitrile it is relatively small (0.02 to 0.06); for long-chain acids moderately large (myristic acid 0.25, pentadecylic acid 0.35); and for esters large (ethyl margarate, 2.1).

Adam and Harding have found the intermediate phase of a margaric nitrile monolayer to be heterogeneous. This would indicate a first order change. How-

FIGURE 11. Monolayers of palmitic (16-carbon) acid. Liquid condensed (L_c) film at 15.79 and 19.29° C.

ever, this behavior, which would indicate an infinite compressibility, does not seem to accord with the relatively low value of the compressibility found for octadecane nitrile by Harkins and Copeland.

Effect of Absence of Hydrogen Bonds in a Monolayer

Since in monolayers of the long-chain alcohols and acids the polar groups are oriented toward the water, they are also brought close together, if the film is condensed. With either of these substances there is a possibility that there may be hydrogen bonding either in (1) the film itself, or (2) between polar groups in the film and molecules of water.

It is, therefore, of interest to learn the effect, produced upon the molecular area, by the elimination of the first possibility, that is, of hydrogen bonding in the film. This may be eliminated by the use of a long-chain nitrile.

The pressure-area-temperature relations obtained with monolayers of octadecane nitrile are exhibited in Fig. 12. From this figure it is evident that the $-\text{CN}$ group gives a much higher area (with a minimum of 25.82 \AA^2 at 15.1°) in the monolayer than either $-\text{CO} \cdot \text{OH}$ or $-\text{OH}$. Adam explains the relations on the basis of the assumption that the nitrile group is the largest, and the hydroxyl group the smallest

FIGURE 12. Monolayers of octadecane-nitrile on water. The intermediate phase exhibits a lower compressibility than that of the acids.

of the three. However, it does not seem possible that the nitrile group, with its two atoms and a carbon-nitrogen distance of only 1.15 Å, can be larger than the carboxyl group with its content of four atoms, even though one (H) of the latter is small. Therefore it seems necessary to reject Adam's hypothesis, and to seek another cause for the high area in the nitrile monolayers. Obviously if there is intramonolayer hydrogen bonding in the case of the acids and alcohols, its absence in the nitrile films would give a sufficient explanation of their higher areas.

Some investigators assume, without solving the statistical mechanics of the problem, that the dipoles in monolayers of this type always repel each other. If this were assumed, the higher dipole moment of the nitriles (3.56×10^{-18}) as compared with those of the acids (1.4×10^{-18}) and the alcohols (1.7×10^{-18}) would give a sufficient cause for the higher areas exhibited by the nitriles. However, as the presence of dipole repulsion has not been proved, the larger molecular areas of the nitrile monolayers may be due to either or both of the causes considered above.

The Condensed Liquid Phase (Fig. 13)

As the intermediate film is compressed, the pressure rises more and more rapidly and the compressibility decreases until at a point *D*, Fig. 4, the π - σ curve changes to a straight line. If it is considered that a change of phase occurs at *D*, then it is of the third order.

The compressibility of the liquid condensed film which exhibits this linear relation is low—usually between 0.005 and 0.01. The pressure-area relations of the *n*-long chain paraffin acids of from 16 to 20 carbon atoms are shown in Fig. 13, and it may be observed that the molecular area at a given pressure decreases with the length of the chain.

High-pressure Phases: The S, or Solid Phase, and the LS Phase of Highly Abnormal Viscosity

If a liquid condensed monolayer is compressed isothermally, it finally reaches an area sufficiently low to give a change of phase into what has usually been designated as a solid film. The phase which is formed is characterized by a compressibility only about an eighth as great as that of the liquid monolayer from which it is formed.

FIGURE 13. Effect of increasing chain length in decreasing the molecular area in liquid condensed (L_c) monolayers of the long chain acids of from 16 to 20 carbon atoms.

If this change of phase is considered as a freezing of the film, it is somewhat surprising to find that freezing or melting occur without latent heat. That is, the latent heat of fusion is zero, and this indicates that the change is a phase transformation of the second order.

The pressure at which this transition occurs depends upon the temperature, and in the case of an n -straight-chain paraffin derivative, is highly dependent upon the nature of the end group. Thus the pressure of the transition is much higher for acids than for alcohols.

Ideas concerning the "solid" phase were in a very confused state until recently, when Harkins and Copeland⁸⁸ discovered that there are two high-pressure phases

instead of one. Both of these have about the same compressibility; but the phase which the more nearly resembles a solid (*S* phase) is characterized by a lower molecular area than the new *LS* phase. The only organic compounds which have thus far been investigated sufficiently to show a distinction between the *S* and the *LS* phases are the *n*-long-chain paraffin alcohols.

While these two phases are most easily distinguished by the great differences exhibited by their viscosities, the probable existence of two phases instead of one was indicated in experiments designed to discover a first order change in a condensed monolayer.

A First Order Change in a Non-gaseous Monolayer

To those who are accustomed to consider only three-dimensional systems, the phase relations in two dimensions appear anomalous. Thus, a change from three to two dimensions, that is, a loss of one dimension, results in an increase of one in the order of a phase change of a condensed system.

FIGURE 14a. Pressure-area temperature relations of condensed monolayers of octadecanol on water. The insert gives an enlarged section in the region of the first-order transition. Outside of this region all of the transitions are second-order. The temperatures ($^{\circ}\text{C}$) for the curves in the principal diagram are: 1, 2.85; 2, 5.10; 3, 7.10; 4, 8.62; 5, 9.90; 6, 12.32; 7, 14.06; 8, 16.04; 9, 18.08; 10, 19.85; 11, 22.95; 12, 25.12; 13, 30.30; 14, 34.85. Curves for four other temperatures are given in the insert. Correction: Multiply Surface Pressures by 0.9315.

This would not be difficult to understand if a two-dimensional film or monolayer were suspended in space, since in such a case, molecular binding in the third direction would be absent, and this would be very likely to involve an increase in the order of a change of phase. The fact that this occurs, even when an aqueous subphase is present, indicates that the binding to the subphase is sufficiently loose to allow the increase of order which is observed.

FIGURE 14b. Pressure-area temperature relations for the normal long-chain paraffin alcohols with 19 and 20 carbon atoms in the chain. The temperature of the first-order transition increases 5° while the pressure rises about 2 dyne cm^{-1} for each additional carbon atom. Correction: Multiply Film Pressures by 0.9315.

It is shown in Fig. 14a that in a narrow range of temperature near 10° C the π - σ curve is flat over a range of area of about 0.2 \AA^2 . This flatness is characteristic of a first order change. The latent heat of this change is very small and varies from 20 to 40 cal. per molecule. This is absorbed in passing from the low- to the high-pressure modification, as in the change from ice to water.

The regions of temperature and pressure in which the liquid condensed (L_c), the LS , and the S phases are stable are shown in Fig. 15, and those of temperature and molecular area in Fig. 16. The variation of pressure with temperature seems to be nearly linear for the second order changes, but is a region with a curved boundary for the first order.

The extremely interesting relation shown in Fig. 15 is that the boundary between the S and the LS phases of octadecanol lies at almost a *constant molecular area* of 19.98 \AA^2 . Thus whether the film is in the LS or the S state is *highly dependent upon the distance between the molecules*.

FIGURE 15. Pressure-temperature values for the phase boundaries of condensed monolayers of octadecanol. Transitions $L_c \rightleftharpoons LS$ are *first-order* from the triple point at 7.5°C on the descending curve to about 11°C , and become *second-order* above this. Transitions $L_c \rightleftharpoons S$ are *second-order*. Multiply pressure by 0.9315.

FIGURE 16. Molecular area-temperature values for the phase boundaries of condensed monolayers of octadecanol. The dotted line gives values at 16 dyne cm^{-1} as obtained by increase of the temperature of a monolayer. The black circles give values at the same pressure, from the isotherms. Multiply P by .93.

The *LS* phase exhibits highly abnormal viscosity relations, discussed in the section on viscosity, and both of the high-pressure monolayers are characterized by an extremely large heat of expansion per unit area, as shown in the section on thermodynamic relations.

THE FILM BALANCE AND ACCESSORIES

The Trough

In 1891 Agnes Pockels initiated the use of a long rectangular trough, filled with water to the brim, for the investigation of the surface tension relations of films of oil. The surface of the water was cleaned by "sweeping" or "scraping" the surface by a transverse barrier which consisted of a narrow sheet of metal 1.5 cm wide. In the work of the writer the trough is shallow, about 6 mm deep, and the water rises about 6 mm above the level of its edges. It is made of stainless steel, and has a hollow bottom, through which an aqueous ethylene glycol solution is pumped from the thermostat which surrounds the trough. A trough which is inside an air thermostat, but not in contact with the thermostat water, is entirely unsuitable. Proper temperature control with such an arrangement is impossible, since (1) it takes an extremely long time to establish temperature equilibrium between a gas and a considerable body of liquid and solid, and (2) the water in the trough is subject to increases or decreases of temperature due to lack of equilibrium between the water vapor in the thermostat and the water in the trough, and this in turn is affected greatly by changes in temperature.

The barriers of paraffined glass or stainless steel are lifted or moved along the surface by the use of slots operated by levers and screws. The screws used for the measurement of the length of the film have a pitch of about 1 mm per turn, and are provided with a vernier to estimate the fractions of a turn; those used for sweeping have a pitch of about 1 cm per turn.

Film Balances

Film balances were used in the last decade of the 19th century by Agnes Pockels and by Lord Rayleigh. Any device which measures directly the difference between two surface tensions, $\gamma_1 - \gamma_2$, and commonly to obtain $\gamma_w - \gamma_f = \pi$, may be considered as a film balance. Here γ_w is the surface tension of the pure liquid, usually water, γ_f is the surface tension of the film-covered surface, and π is by *definition*, the film pressure.

Vertical Pull Film Balance (Fig. 17). The simplest, cheapest, and most widely applicable film balance is one in which the film-covered surface of the water in the trough exerts a vertical downward pull upon a sheet of solid material, such as glass, quartz, or metal, whose contact angle toward the surface of the liquid is zero. A convenient solid sheet is a microscopic slide or cover glass of quartz or glass, or a thin, plane sheet of platinum. Since the sensitivity of the method is (nearly) inversely proportional to the thickness of the sheet, an extremely thin sheet of platinum may be used when it is desired to obtain the film pressure to $0.001 \text{ dyne cm}^{-1}$ or less.

The decrease in the downward pull on the sheet is measured by the deflection of the beam of an analytical balance, from one arm of which the slide or sheet is hung in such a way that its surface is partly below and partly above the surface of the water.

An apparatus of this type was used very early by Wilhelmy to measure the surface tension of liquids, but on account of the inherent difficulties of his method, it has remained almost unused. If, however, the process of measurement is changed into the differential form needed for the measurement of the surface pressure, all the serious difficulties and errors disappear.

Film balances of this type have been used both by Harkins and Myers, and by

Dervichian. The latter constructed such a balance in a form designed to give continuous rapid recording of the film pressure and area on photographic paper. This form is valuable in the study of monolayers which collapse rapidly. A different automatic type of recording has been used in this laboratory in the study of the penetration of films of cetyl alcohol by cetyl sodium sulfate. The phenomenon of penetration was discovered by Schulman, but he failed to realize that at large molecular areas of the alcohol the penetration is an extremely slow process, and as a consequence many of his values are extremely far from those attained at equilibrium.

FIGURE 17. Vertical type of film balance for the measurement of the film pressure of soluble and insoluble films. (The balance is kept on the closed top of the thermostat, while the trough and film are inside.)

In order to obtain the rate at which equilibrium is attained in this slow process, Gordon and Harkins use a motion-picture camera which photographs the position of a line of light on a long, graduated scale at satisfactory intervals of time, *e.g.* every five minutes. Very accurate measurements are obtained in this way over periods of many hours. If the changes of pressure are rapid, the motion-picture camera may be operated at normal speed.

The vertical film balance exhibits the following advantages over the horizontal type commonly used:

It is much cheaper for any given accuracy.

It is much simpler and may be installed in a few minutes, since an ordinary balance and a microscope slide give results of a high degree of accuracy.

It is specially useful in investigations in which ions of the metals have a deleterious effect, since it is extremely easy to use a slide, barriers, and trough which consist wholly of quartz, so that the solution and its surface come into contact with quartz alone.

In a simple form it will give the film pressure of a soluble film, while the use of the horizontal types involves the very elaborate movable partition of the PLAWM* trough of McBain.

The perimeter p of a slide or sheet w cm wide and t cm thick, is $2(w + t)$, and, with a zero contact angle the downward pull of the surface on the slide is $2(w + t)$ or p . Let W be the apparent weight in grams of the slide partly immersed in water. If the surface tension is reduced by the spreading of a film, the slide rises until the decrease in downward pull ($-F_d$) is balanced by the decrease of buoyancy ($-F_u$) of the submerged portion of the slides, or

$$\Delta F_d = \Delta F_u \quad (24)$$

$$2p\Delta\gamma = gptw\Delta h \quad (25)$$

where g is the acceleration of gravity, and Δh is the change in height of the slide measured by the use of a cathetometer. In practice it is much simpler to mount a galvanometer mirror with its center in the axis of rotation of the beam, and to observe the deflection of the beam by a telescope and illuminated scale, or to use a beam of light and observe its deflection on a scale. For a segment of a circular scale, Δh is proportional to ΔS , the change in the scale reading, or

$$-p\Delta\gamma = k\Delta S \quad (26)$$

where the value of the constant k is determined by observing the values of ΔS associated with different weights on the balance pan with the slide immersed in water which has a clean surface.

$$k = -g\Delta M/\Delta S \quad (27)$$

Thus the reduction in the surface tension, $\Delta\gamma$, which is the film pressure π , caused by spreading and compressing the film, is

$$\pi = \Delta\gamma = k\Delta S/2p \quad (28)$$

In the determination of the film pressure of a soluble substance the trough is filled with pure water, the surface is swept, and the scale reading of the beam of light is set to zero. Then either of two procedures may be followed:

(1) The solute is added and the solution stirred until the concentration is uniform throughout. The surface is swept again, and the scale reading, taken when equilibrium is attained, gives the film pressure.

(2) The pure water is removed from the trough, and replaced by exactly the same volume of solution. The equilibrium scale reading gives the film pressure, as in (1).

Surface-active solutes are often present at such great dilutions that no corrections for differences of density are needed, but with more concentrated solutions such corrections should be applied.

In a second type of vertical film balance a slide, hung from one end of the balance beam, is suspended in clean water, and another slide, from the other end of the beam, is suspended in the solution.

Horizontal Float Film Balance. In the horizontal float film balance designed by Langmuir, and improved by Adam and by others, the clean surface of the water is separated from that covered by the film by a floating barrier or "float" of paraffined metal, glass, or mica. The great improvement introduced by Adam was to prevent the film from flowing around each end of the float by an extremely thin sheet of gold

* PLAWM = Pockels, Langmuir, Adam, Wilson, McBain.

FIGURE 19. Film Balance (1932 model) with apparatus for surveying the surface with a polonium coated electrode.

potential at any part of the film, and a second electrode, not shown, served to determine the potential of the clean surface of the water. Fig. 20 is a photograph of the film balance of Harkins and Myers, which was inclosed in an air thermostat.

FIGURE 20. Trough and Film Balance (1934 model) inside air thermostat. The new model (1941) is buried inside a water thermostat and the sweeping is carried out by screws of 1 cm per turn which replace the rods at *D* while the barrier used to change the area of the film is moved by the fine screw shown here directly underneath the trough. The trough *E* contains a supply of clean water into which large sheets of filter paper (not shown) are dipped. This is done in order to saturate the air with water vapor.

The Thermostat (Fig. 21). Even though it is not possible to obtain accurate data on the pressure-area relations of monolayers without an accurate regulation of the temperature of the surface of the water in the trough, almost all the work on this subject has been carried out either without the use of a thermostat at all, or with only the bottom of the trough in contact with the water of a thermostat. It is not generally realized that the control of the temperature of the surface of water is very much more difficult than that of the water itself.

In the design of a thermostat for work on films it seems best to use an air thermostat which is entirely buried in the center of a liquid-filled thermostat, in order to cause the temperature of the radiation which strikes the surface of the liquid to be the same as that of the air chamber. This chamber should be saturated,

FIGURE 21. Liquid-filled thermostat, for accurate work at temperatures from -30°C to $+70^{\circ}\text{C}$.

but not supersaturated, with water vapor. To produce this saturation water surfaces of large area, other than that of the water in the trough, should be used. Large sheets of filter paper which dip into clean water in a vessel of large area are used by the writer.

A thermostat of this type with an inner chamber $112 \times 66 \times 41$ cm, was constructed by Harkins and Copeland (Fig. 21). This air chamber is surrounded on the bottom, top, and four sides by hollow metal walls 10 to 20 cm thick, and these are filled with an aqueous solution of ethylene glycol. The only thinner section is the glass door, which is hollow, but only 2.5 cm thick. The solution of the thermostat is pumped through this door, and also through the hollow bottom of the metal trough used for the film.

The solution in the thermostat is heated by a heating coil and cooled by a coil from a bath cooled by a refrigerating machine. This makes it possible to investigate monolayers on salt solutions at temperatures far below 0°C .

The temperature is kept constant to $\pm 0.001^{\circ}\text{C}$ by a mercury regulator which operates a heater by a vacuum tube-relay circuit.

The film balances, one each of the horizontal and of the vertical type, are operated by rods or wires which pass through tubes between the outer and inner walls of the thermostat. The controls are elaborate and will be described elsewhere.

General Relations

If a small sheet of silver or some other metal is fastened parallel to and a short distance above a clean water surface, the potential between the two may be changed by as much as 0.95 volt, or approximately by the potential of an Edison cell, if a monolayer of oil spreads over the surface of the water underneath the electrode. This difference of potential may be determined by the use of a Compton electrometer with a potentiometric system, if the air under the electrode is made into an electrically conducting medium, as by a deposit of polonium on the electrode. It may also be obtained if the electrical capacity is changed rapidly, as by the use of the vibrating electrode of Zisman, who used a vacuum-tube circuit, with a frequency determined by a crystal.

If the electrode is placed at first over a clean water surface, and then over the same surface covered by a liquid condensed (L_c) monolayer of stearic acid, the change of potential is found to be close to 400 mV, and it is said that the *surface potential* is 400 mV.

The earliest determination of the surface potential seems to be that of Bichat and Blondlot, while Kenrick extended the work in 1896. Frumkin and Guyot have made notable contributions to the subject.

The potential difference (ΔV) between two parallel plane *metal* plates of an ordinary parallel plate condenser, with a unit dielectric constant, is

$$\Delta V = 4\pi\sigma s \quad (29)$$

in which σ is the surface density of the charge and s is the distance between the plates.

Since $\sigma = ne$, where n is the number of electronic charges per sq cm and e is the electronic charge,

$$V = 4\pi n(es) = 4\pi n\bar{m} \quad (30)$$

in which \bar{m} is the product of the value of the electronic charge by the distance between the plates.

Schulman and Rideal considered that this equation, which they attribute to Helmholtz, may be applied to calculate the dipole moment of the molecules of the film on the basis that $\mu_s = \bar{m}$ if n is considered as the number of molecules in one sq cm of film. Thus

$$\mu_s = \Delta V / 4\pi n \quad (31)$$

It is found, however, that the value thus obtained is only about one-sixth, or even one-tenth that determined by the standard methods for the dipole moments of molecules which contain the same polar groups.

In 1914 the writer assumed that in monolayers of oleic or stearic acid, or other polar-nonpolar molecules, the polar groups are oriented toward the water, and it may be assumed that it is their polar groups which give a part of the contact potential. However, these polar groups, by their dipole moments, orient the water molecules underneath them. There is thus an interaction between the polar $-\text{COOH}$ groups and the molecules of water, between the $-\text{COOH}$ groups themselves and between the dipoles of the water molecules. Those who have applied this simple equation have not made any attempt to solve the statistical-mechanical problem involved in order to show whether or not the apparent positive charges of the $-\text{COOH}$ dipoles lie in a single plane and the negative charges in another. Thus, at the present time the equation

$$\mu_s = \Delta V / 4\pi n \quad (32)$$

has no special significance.

However, it is to be expected that on the whole the surface potential should increase with the number of dipoles per unit area of monolayer, so that in the equation

$$m = \Delta V/n \quad (33)$$

the value of m should be much more constant than that of ΔV ; and since $\frac{1}{4}\pi$ is a constant, μ_s should also be very much more constant than ΔV , but this does not cause either m or μ_s to be a dipole moment.

In 1928 it was suggested to Frumkin by the writer that the great discrepancies in the values of the surface potential as obtained by various observers, or even a single observer, at that time, were not due to any fault of the method, but rather to the lack

FIGURE 23. Pressure-area and potential-area of myristic acid monolayers. At areas greater than $52 \text{ Å}^2 \text{ molecule}^{-1}$ the film is heterogeneous (gaseous and liquid-expanded).

of knowledge of what phase of the film was present under the electrode. This idea led to the use of an electrode which could be moved in such a way as to survey the entire surface, as in the apparatus of Harkins and Fischer.⁴⁹

The use of this type of electrode gave definite evidence that the region L_G in Fig. 6 represents a heterogeneous film, which consists of islands of liquid-expanded film in a sea of gaseous film at lower temperatures or with longer molecules; the islands may be in the liquid condensed, or in the solid state. The results of the surface potential survey of several monolayers are given in Fig. 22.

This survey of a monolayer of myristic acid at a mean molecular area of 56.5 Å^2 at 17°C gave a surface potential of zero at one position close to the movable barrier, and this value indicates that nothing but gaseous film was underneath the electrode (area *ca.* 0.7 cm^2) in this position. The most concentrated part of the monolayer was adjacent to the float and exhibited a potential of 199 mv. This is the potential of the liquid expanded phase, since at an area of 37.1 Å^2 the potential was not larger than this. At a molecular area of 25.0 Å^2 , where the film is in the intermediate state, the potential was more constant but varied from 248 to 281 mv.

At 23° C the monolayer of palmitic acid at 48 Å² is partly in the gaseous state and partly in the liquid condensed state with a maximum surface potential of 330 mv. The lower potentials, as low as 35 mv, indicate that most of the area under the electrode is covered by gaseous film.

Fig. 23 exhibits the pressure-area and potential-area relations of a monolayer of myristic acid at about 15° C. At mean molecular areas above about 47 Å² the surface potential seems to have an upper limit of about 160 mv and a lower limit which decreases as the area rises. This behavior is due to the heterogeneity of the film above 47 Å², and the maximum potential possible is that of the liquid expanded

FIGURE 24. Potential (V)-area and pressure-area relations of monolayers of eicosanol (20-carbon alcohol) at 25° C.

film. The lower limit is determined by the lowest mean density of the film which can be obtained under the electrode. It is obvious that, as the mean molecular area increases, it is possible to get more and more gaseous film under the electrode, and thus obtain a smaller surface potential.

It is apparent from the figure that the curve for the variation of surface potential with area gives no indication of the second order transition between liquid expanded and intermediate film, which is so apparent in the pressure-area curve. A similar relation is exhibited in Fig. 24, which gives no indication of the first-order transition in the pressure (π)-potential (V) curve, though it is very apparent in the relation between pressure and area.

Effect of Double Bonds on the Surface Potentials of Polycyclic Compounds (*d*-Pimeric and Tetrahydro-*d*-Pimeric Acids)

The three-ring compounds, *d*-pimeric and tetrahydro-*d*-pimeric acids, are related in structure to cholesterol and to certain hormones and vitamins. In their condensed monolayers the molecules are oriented with their long axes nearly per-

pendicular to the surface of the water and the maximum thickness of the film is 12 Å, or half the length of the stearic acid molecule, while the molecular area of these compounds is, at film collapse, about 2.3 times higher than that of this acid. At a film pressure of 5 dyne cm^{-1} the molecular areas are equal (51 Å²) but the compressibility of the monolayer of the unsaturated (0.0101) is much higher (Fig. 25) than that of the saturated (0.007) compound.

FIGURE 25. Pressure-area and potential-area relations of three ring compounds: I. *d*-pimeric acid (saturated) and II, tetrahydro-*d*-pimeric acid (see Fig. 26). Note that the double bonds of II reduce the surface potential to about 50 per cent of that of I, and that the double bonds greatly increase the compressibility.

The molecule of *d*-pimeric acid contains two double bonds which lie at the "top" of the molecule, if it is oriented as it is supposed to be in a tightly packed, condensed film. The effect of these double bonds on the surface potential is extremely interesting. Since the surface potential of unsaturated is less than half that of the saturated compound, the dipoles due to unsaturation seem to be opposed to those of the carboxyl group. Furthermore, while the surface potential of the saturated compound rises as the film becomes more tightly packed, that of the unsaturated compound

decreases with packing. The former normal effect is due largely to an increase in the number of dipoles with pressure. The latter indicates that increased tightness of packing increases the opposition of the dipoles.

It has been seen that unsaturation at the "top" of the molecules increases the tightness of packing at the highest pressure (17 dynes per sq cm) and gives a molecular area of 43 \AA^2 . Measurements with molecular models for these compounds gave an area of 42 \AA^2 for tight packing if the molecule is oriented as in Fig. 26. If the carboxyl group were in position 3 the orientation should be different, and the molecular models for this case gave an area of 37 \AA^2 , which is much less than that which actually was found.

At a low film pressure the unsaturated groups near the "top" of the molecule change the molecular area in the opposite direction; that is, they cause a slight expansion of the film, presumably because the "tops" of some of the molecules are pulled downward toward the water by the dipoles of the unsaturated groups.

FIGURE 26. Structural formulas of the pimeric acids.

THE COMPRESSIBILITY OF A MONOLAYER AS RELATED TO ITS PHASE

Of the six phases exhibited by monolayers it is found that three have compressibilities which are almost independent of pressure, whereas the other three show a large pressure effect (Table 5).

Table 5. Variation with Film Pressure of the Compressibility of Monolayer Phases of Normal Long Chain Derivatives

| A. Nearly Constant | B. Highly Variable |
|---|--|
| 1. Liquid-condensed phase $-\kappa = 0.004$ to 0.01 | 4. Gas phase |
| 2. LS phase | 5. Liquid-expanded phase $-\kappa \propto \pi = \text{linear}$ $\kappa = 0.02$ to 0.06 |
| 3. S (or Solid) phase Phases 2 and 3 $-\kappa = 0.0005$ to 0.001 | 6. Intermediate phase $-\kappa = -0.02$ to 2.2 |

While the values of the compressibility are determined mostly by the phase involved, there is also a variation with the nature of the polar group. Thus, in the intermediate phase esters exhibit higher compressibilities than nitriles, and the values for these are higher than for the acids (Table 6).

The compressibility of an L_c monolayer is of the order of ten times that of the solid, that for L_s is of the order of six times that for L_e , and the maximum for the intermediate phase is of the order of eight times that for L_s , while its minimum compressibility is in the limit equal to that of L_c . Since the maximum compressibility of the intermediate phase is somewhat dependent upon the rate of compression, the value for any given substance and temperature is more uncertain than for the other phases.

The compressibility of the liquid (L_s) phase exhibits an interesting relation in

three of the cases thus far investigated. Thus the slope $(\partial\kappa/\partial\sigma)_T$ of the compressibility exhibits two values (Fig. 27). For myristic acid at 16.6° C these are 0.0030

FIGURE 27. Variation of the compressibility of liquid-expanded (L_e) monolayers with molecular area.

in the low-area region (33 to 37.5 Å²) and 0.005 in the high-area region (37.5 to 43.5 Å²); and for pentadecylic acid at 25° C the values are 0.014 (35 to 39.5 Å²) and 0.003 (39.5 to 46 Å²). For tridecylic acid at 12.5° C the change of slope occurs at about 31.5 Å². In the high-area region the compressibility increases much more rapidly as the area approaches closely that at which vaporization begins.

If the above relation could be shown to be general it would indicate a change of a higher order at about the mean molecular area for the L_e film. However, for palmitic acid at 39.85° C the compressibility is linear with respect to area from $-\kappa = 0.016$ at 36 Å² to $-\kappa = 0.032$ at 44.5 Å², and thus does not exhibit the behavior described above. Therefore, it would not seem certain that this is a change of a higher order. However, an indication of a change at just this point has been observed by Dervichian^{6, pp. 933-4} in the fluidity, apparent dipole moment, and compressibility of myristic acid at 38 to 39 Å², of triolein at 3×38.3 Å², and of tricaproin at about the same area. He assumes the change to be of the second order in the case of triolein, and of the third order for tricaproin.

Dervichian's general theory is "that areas corresponding to ordinary phase changes are found as points of discontinuity of higher order in those phases which exist at higher temperatures," while the observations of this laboratory indicate that these areas are not constant, but shift with the temperature or with the number of carbon atoms in the chain.

Dervichian assumes that the discontinuities at 38 to 39 Å² occur at just the area of the triple point, but we obtain the value 43 Å² as the area at the triple point Fig. 10a for the normal acids from tridecylic to palmitic, while as listed above, the apparent discontinuities occur at areas from 31.5 to 39.5 Å², and seem to exhibit an increasing value as the length of the chain increases.

In Table 4 it has been assumed, on the basis of the compressibility and the energy relations, that there is a third (possibly second)-order change at D (Fig. 6) from the liquid condensed (L_c) to the intermediate film. At this point the compressibility, on going from L_c to I , begins to rise with extreme rapidity and often exhibits the particular type of inflection characteristic of a cubic form. The behavior of the compressibility at this point is some evidence in favor of a change of a higher order at this point, as is the behavior of the energy of spreading and extension, as already been pointed out.

From the relations outlined above it is evident that the compressibility is a very important property in the determination of what phase or what change of phase is involved in any definite case. Kirkwood has developed a theory according to which, as a monolayer expands through the intermediate state, there is an increase in the

MONOLAYERS WHOSE MOLECULES LIE FLAT ON THE SURFACE OF WATER

In 1917 Harkins, Davies, and Clark⁶ assumed that in the surfaces of pure liquids or in condensed monolayers on water the molecules are oriented perpendicular to the surface, provided they are long-chain paraffins with a polar group or groups at one end of the molecule. However, they also assumed that a proper distribution of such groups along the chain, or a symmetrical distribution in a ring compound, would give a monolayer in which the molecules lie flat. In order to test the latter hypothesis, long-chain linear ω -hydroxydecanoic acid polymers, with chains from 60 to 1970 Å (0.2 μ) long were obtained from W. H. Carothers. Since in these chains there is one polar group at every tenth carbon atom, the molecules should lie flat on the surface and thus give a tightly packed monolayer about 4.5 Å thick, with about 4.5 Å distance (d) between the centers of the chains. The experiments showed that at a pressure of 3 dynes per cm² the apparent thickness of the films varies from 4.0 to 5.0 Å, while the "width" of the molecule, or the molecular spacing, varies from 4.0 to 4.8 Å. The product of the averages of these linear dimensions is about 20 Å², which may be considered as the area of the cross-section of the molecule perpendicular to its length. Such relationships together with those expressed in Tables 8 and 9 show that these molecules lie flat on the surface.

The pressure-area and potential area relations of these monolayers are shown in Fig. 28. The surface potentials of these extremely thin films are found to be high (*ca* 400 mv).

Table 8. Properties of Films with Different Orientations of the Molecule

Long Axis Vertical
 Molecular area independent of length
 Withstand high pressures (to the order of 15 to 50 dynes per cm)
 Surface potential increases with length of molecules up to 18 carbon atoms
 Compressibility decreases with increasing length of chain

Long Axis Horizontal
 Molecular area increases with length
 Collapse at low pressures (2 to 10 dynes)
 Surface potentials of the same order for long and short molecules
 Compressibility high and independent of length of molecules

Table 9. Films of Polymers of ω -Hydroxydecanoic Acid on Water

THE VISCOSITY OF MONOLAYERS

Viscosity of Monolayers and Canal Viscometers

In the flow of a monolayer of oil under a difference of pressure, the first molecular layer of water under it is carried along with the film, and this in turn affects

the other adjacent layers underneath. Thus the flow of the film is retarded by the viscosity of the water. If the viscosity of the film itself is desired, as in the flow of the film through a narrow and deep canal, a correction term enters, and this involves the first power of η_0 , the viscosity of the water. If the film spreads with sufficient rapidity, and excessive convection can be avoided, the water level can be seen to be momentarily lower at the place where a hexane solution of a polar-non-polar oil was put on the surface than near the outer portion of the spreading film.

This drag on the water is indicated in the correction term in the equation of Harkins, Myers, and Kirkwood⁶⁷ for the viscosity (η) of a monolayer as determined by the flow of the film through a deep canal whose length (l) is large in comparison with its width (a):

$$\eta = \alpha a^3 / 12A - a\eta_0 / \pi$$

Here η_0 is the viscosity of the subphase and α is the pressure gradient $(\pi_2 - \pi_1)/l$ of the film, and A is the area flux. It may be noted that the law of Poiseuille is here modified since, as the flowing body loses one dimension, the power of a is reduced by unity from four to three.

The last or correction term is large in comparison with the viscosity of an expanded liquid film unless the canal is very narrow. On water at 20° C the corrections in surface poises are for canals of different widths:

$$\begin{aligned} 1 \text{ mm} &= 0.00032 \\ 0.5 \text{ mm} &= 0.00016 \\ 0.1 \text{ mm} &= 0.000032 \end{aligned}$$

General Viscosity Relations^{69, 81}

The viscosity of a monolayer is highly dependent both upon the closeness of the molecular packing in the film, and upon the structure of the monolayer otherwise. No measurement of the viscosity of a gaseous film has been made. Liquid-expanded monolayers have higher, but still low, viscosities; those of liquid-condensed films are high, and of S films are anomalous, but often even higher.

Normal Long-Chain Paraffin Acids. The viscosities of monolayers of these acids exhibit remarkable but normal relations, as exhibited in Fig. 29. At the lower pressures the monolayers are in the liquid-condensed state, but at the high pressures they are in the S state. The normal behavior is that of the acids of 18, 19, and 20 carbon atoms per molecule, since the films of the shorter-chain acids are not sufficiently removed from the *intermediate* state to have wholly the properties of the liquid-condensed state.

Use of Viscosity Measurements in the Detection of Phase Transitions. The second-order transition from the condensed liquid to the S state, in the case of these acids, occurs at what is the intersection of two straight lines in the pressure-area (π, σ) diagram. Thus, in approaching the transition from either side of the pressure-area diagram, there is no hint of its existence until the point itself is reached. In the case of the viscosity, however, it is apparent from Fig. 29 that the linear relation between $\log \eta$ and begins to disappear at a pressure several dynes away from that of the transition.

The most important viscosity relations of these acids on an aqueous subphase of pH 2 are given below:

(1) From the lowest pressures investigated up to 19 dynes per cm or more, the logarithm of the surface viscosity is proportional to the film pressure, or

$$\log \eta = \log \eta_0 + k\pi \quad (33a)$$

for all the acids from 16 to 20 carbon atoms.

(2) The viscosity of the liquid films increases rapidly with the length of the hydrocarbon chain.

FIGURE 29. Viscosity-pressure relations of monolayers of the normal long-paraffin chain fatty acids.

- (3) The liquid or low pressure-condensed films exhibit Newtonian viscosity.
- (4) The viscosity of the "plastic" (or high pressure-condensed) films decreases with the length of the hydrocarbon chain.
- (5) Films designated as "plastic" exhibit *non-Newtonian* viscosity, that is, the *viscosity varies with the rate of shear*.
- (6) The film viscosity begins to increase more rapidly than corresponds to eq. (33a) at a pressure considerably below that of the sharp kink in the film-pressure-area curve. Also, the rise in viscosity between the low pressure-condensed film is larger, the shorter the hydrocarbon chain of the fatty acid.
- (7) Above the transition pressure the surface viscosity increases less rapidly until it approaches some degree of constancy.
- (8) The viscosities of the monolayers of the acids are very much less than those of the corresponding alcohols. Thus, at four dynes per cm pressure, with 16 carbon atoms in the molecule, the alcohol film is of the order of 33 times more viscous than that of the acid; with 17 carbon atoms the factor is the same; with 18 carbon atoms it falls to 17 times that of the acid.

Viscosity Relations of the *n*-Long Alcohols of from 14 to 20 Carbon Atoms per Molecule

An investigation of the monolayers of the *n*-long chain alcohols by Fourt and Harkins⁶⁹ at 25° C show that at this temperature the relations are very much the same as those exhibited by the acids, except that, as mentioned above, the viscosities are from 17 to 33 times higher than those of acids of the same chain length.

It was found that the viscosities of the alcohols of from 14 to 18 carbon atoms,

when calculated as bulk viscosities, are from ten thousand to a hundred million times larger than the viscosity of water at the same temperature.

The normal viscosity relations exhibited by these alcohols at 25° C (Fig. 30) become anomalous and remarkable when the temperature range of the experiments is extended to that between 5.0 and 50° C.

ABNORMAL VARIATION OF THE VISCOSITY OF LIQUID-CONDENSED
PHASE OF AN ALCOHOL WITH TEMPERATURE AND PRESSURE
(FIGS. 31, 32, AND 33 AND TABLE 10.)⁹⁶

FIGURE 30. Viscosity-pressure relations of the normal chain alcohols at 25° C.

Effect of Temperature

At very low film pressures the viscosity of the liquid condensed (L_c) monolayer of a normal long-chain paraffin alcohol decreases with increasing temperature, as is normal. Thus the value is about seven times lower at 25° C than at 5° C. However, in Fig. 31 the curves for this phase are seen to cross each other at higher pressures, with the result that at the highest pressures at which this phase exists the viscosity in surface poises decreases from a little over 0.1 at 25° C to about 0.0045 at 8.85° C, or to about a twenty-fifth of its value in a decrease of temperature of 16° C. This is extremely remarkable, since in general the viscosity of a phase rises rapidly as the temperature is decreased.

^a Note that at a film pressure of one dyne per cm the viscosity decreases with increasing temperature, as is normal, from 0.150 poise at 5.1° to 0.0192 at 25° C. At 10 dynes per cm the viscosity decreases (normal) from 0.352 at 5.1° to 0.0096 poise at 12.2° C, but increases (abnormal) from this temperature up to 0.0570 at 25° C. In all of the above changes the monolayer is in the liquid

FIGURE 32. Viscosity relations of the liquid condensed (L_c), and the LS end phases of octadecanol between 5.0°C and 8.85° C. Multiply all pressures for the alcohols by 0.931.

As the temperature is decreased still further (Fig. 32), the viscosity of the liquid condensed (L_c) phase, at the highest pressures at which it exists, increases from about 0.045 at 8.85° C to about one surface poise, or the increase is by a factor of about 200 for a temperature increment of 4° C.

Effect of Pressure

At both 5 and 25° C the effect of pressure upon the viscosity of the L_c film of octadecanol may be described as normal. As the temperature rises from the lower or falls from the higher value, the effect becomes increasingly abnormal as 9° C is approached. At 9.97° C the viscosity decreases with increasing rapidly, from about 0.04 at low pressure to 0.005 surface poise at a pressure of 12 dynes cm^{-1} . At 8.10° C the decrease is from 0.07 to slightly below 0.006 surface poise by an increase

condensed (L_2) state. At 18 dyne cm^{-1} the viscosity in the S state decreases with extreme rapidity with increase of temperature, from 2.65 poises at 5.1° to 0.0890 poise at 7.2° and still lower. Then a transition to the LS state occurs, after which the viscosity falls much more slowly to a minimum of not far from 0.0044 poise at about 8.8° C. Then the direction of the change changes and the viscosity of the LS phase increases rapidly with increase of temperature (abnormal) until it becomes 0.249 at 25° C.

FIGURE 33. Viscosity relations of the liquid condensed and LS phases of octadecanol between 30° and 54° C. The extremely abnormal relations of Figures 31 and 32 have disappeared, since the viscosity again falls with rise of temperature. It is remarkable that identical values of viscosity and pressure occur at three different temperatures. Multiply all pressures for alcohols by 0.931.

of pressure to 13 dynes cm^{-1} . This behavior is extremely abnormal since the viscosity is reduced to an eighth or tenth of its value by an increase of pressure which should give threefold or fourfold increase.

A SUPERLIQUID PHASE WITH EXTREMELY ABNORMAL VISCOSITY RELATIONS

Figs. 31, 32 and 33 indicate the existence of a new phase which exhibits extremely remarkable viscosity relations as follows:

(1) Although the viscosity is Newtonian, it is essentially independent of pressure. In this constancy of viscosity with increase of pressure, it resembles solid monolayers, which, however, have non-Newtonian viscosity.

(2) Although the phase exists in the same range of high pressures as the S (usually designated as solid) phase, its viscosity at temperatures of 8 to 12° C is much lower than that exhibited at low pressures by the liquid (L_c) phase from which it is formed by increase of pressure.

(3) The viscosity of this phase is lowest at those temperatures at which it is formed by a *first-order* transition from the liquid-condensed (L_c) phase, by increase of pressure.

(4) As the temperature is increased in the range of the second-order transition $L_c \rightleftharpoons LS$, the viscosity rises very rapidly and takes on more and more the characteristics commonly exhibited by the S phase, although there seems to be no indication of any change of phase. At 25° C the viscosity of the LS phase has become non-Newtonian, high (ca. 0.25 surface poise), and decreases slightly with increase of

pressure. Since the viscosity is non-Newtonian, the value cited refers to the rate of shear employed in this work. A Couette type of apparatus has been designed and will be used later to determine the relation between viscosity and rate of shear.

THE TRANSITION $L_o \rightleftharpoons LS$ AND $LS \rightleftharpoons S$ AS REVEALED BY ABRUPT CHANGES IN VISCOSITY

Between 8 and 10° C (Figs. 31 and 32) the slope ($\partial \log \eta / \partial \pi$) takes on an extremely large negative value as the pressure approaches about 13 dynes cm^{-1} , but at this pressure changes abruptly to zero. The pressures and temperatures of these abrupt changes correspond to phase transitions from the condensed liquid to a high pressure phase as revealed by the pressure-area (π , σ) diagram of Fig. 15. At 8.10, 8.40, 8.85, and 9.97° C the viscosity remains constant for increases of pressure of 4, 5.5, 11, and more than 22 dynes cm^{-1} , respectively.

At all of these temperatures except the highest, the viscosity begins to increase rapidly at the end of these intervals, and at 8.10 and 8.40° C the slope of the curve takes on an almost infinite *positive* value, after which it decreases, but remains high.

The most obvious explanation of this extremely high slope is that it corresponds to a phase transition, which would seem to be from the LS to the S phase. This assumption is the basis for the inclusion in Figs. 15 and 16 of a boundary between these two phases, which, as obtained from the viscosity relations, is found to be linear, with a slope which indicates a rise in the transition pressure of 6.4 dynes cm^{-1} per ° C.

The evidence for the existence of the transition from the LS to the S phase is not that of the viscosity alone, since the effect of the transition is apparent in the entropy and energy relations. These exhibit discontinuities at this transition, and also at that between the L_o and S phases. At a molecular area of 19.98 \AA^2 the $L_o \rightleftharpoons S$ transition occurs at a pressure of 17.61 dynes cm^{-1} , and the $LS \rightleftharpoons S$ transition at 23.73 dynes cm^{-1} . These pressures agree with those obtained from the viscosity relations.

The alcohols of 18, 19 and 20 carbon atoms per molecule give similar pressure-area diagrams, but the temperature of the first-order transition rises about 5° C for each additional carbon atom.

DISCUSSION

The molecular area at which the transition $LS \rightleftharpoons S$ occurs in octadecanol seems to be almost independent of pressure and temperature, and what little work has already been done with the 20-carbon alcohol seems to indicate that the area for its similar transition is almost the same. Also, the range in area of the first-order transition seems to be affected only slightly by an increase in the number of carbon atoms, while both the pressure and the temperature are increased materially. These facts seem to suggest that the mechanism involved is extremely sensitive to the distance between the molecules in the monolayer. Furthermore, since similar abnormalities in pure three-dimensional liquids involve only minor changes of viscosity, the enormous effects found here would seem to be associated with the presence of the aqueous subphase. This can effect the relation in two ways:

(1) By orientation of the molecules, the hydroxyl groups (also the hydrocarbon chains) of the alcohols are brought into proximity.

(2) The hydroxyl groups are brought into contact with molecules of water.

By (1) there could be some type of bonding between the hydroxyl groups of the alcohols, or by (2) between these groups and the water.

To explain the results, it is necessary to assume a type of bonding which is extremely sensitive to changes of intermolecular distance. In either (1) or (2) hydrogen bonding is likely to be involved. The transition $S \rightleftharpoons LS$ takes place at a molecular area not far from 19.98 \AA^2 at any pressure at which both phases are stable.

This corresponds to a temperature close to 8.6°C . The curve nearest to this temperature in Fig. 32 is that at 7.2°C , at which temperature the viscosity of the L_c phase is almost constant, with increase of pressure up to 9 dynes cm^{-1} and then decreases more and more rapidly until at 14 dynes cm^{-1} the monolayer changes directly into the S phase. At the transition point the viscosity is slightly less than 0.03 surface poise, but that of the S phase rises rapidly with pressure, until at $25.5\text{ dynes cm}^{-1}$ it is 0.5 surface poise.

At 8.85°C and 16 dynes cm^{-1} the molecular area is 20.0 \AA^2 and the viscosity, which is that of the LS phase, is 0.0044 surface poise. If at this pressure the molecular area of this phase is increased to 20.75 \AA^2 by increase of temperature, the viscosity increases by a factor of 55 to 0.2400 . *Thus the binding is increased greatly by an increase of molecular area and temperature, both of which should normally decrease it very greatly.*

The extremely high fluidity of the LS film is exhibited only when the molecules are tightly packed and when the temperature is relatively low. Increase of molecular distance is accompanied by an extremely rapid rise of viscosity. Thus at a pressure of 16 dynes cm^{-1} the viscosity is increased 55 times by *increase* of 0.07 \AA in mean molecular distance.

While the viscosity of the condensed liquid (L_c) phase of the alcohols decreases at low pressures with the temperature, which is normal, this is reversed at high pressures. At higher and lower temperatures, increase of pressure gives the normal increase of viscosity with pressure, but at intermediate temperatures the viscosity decreases more and more rapidly as the pressure increases, until finally a phase transformation occurs.

NON-EQUILIBRIUM RELATIONS BETWEEN A SLIGHTLY SOLUBLE MONOLAYER AND ITS AQUEOUS SUBPHASE AS EXHIBITED BY FILM PRESSURE (π) AND SURFACE POTENTIAL (V)⁶⁰

If the monolayer of a slightly soluble monolayer is compressed rapidly, the film pressure is increased and the surface potential is changed. The sign of both these changes is reversed if the film is more or less completely removed by sweeping. If the monolayer consists of lauric acid the return to equilibrium at 25°C involves a period of time of the order of a half hour. However, Fig. 34 indicates that the film pressure (F) returns (increases) to its equilibrium value much more slowly than the surface potential. It should be noted that sweeping reduces the film potential to that of the clean surface of water.

EFFECT OF BIVALENT POSITIVE IONS ON MONOLAYERS OF THE N-LONG CHAIN PARAFFIN ACIDS AND OF SOAPS: BIOLOGICAL EFFECTS

The remarkable effects of sodium hydroxide, sodium chloride, and calcium chloride upon an interfacial film of oleic acid were discovered by Clowes,* and were found to be even more remarkable when investigated quantitatively by Harkins and Zollman.²⁹ The interfacial tension between an aqueous solution and a 0.001 molal solution of oleic acid in olive oil was found to be only $0.002\text{ dyne cm}^{-1}$, when the aqueous phase contained 0.001 m NaOH and 0.15 m NaCl . This is the lowest interfacial tension between water and an oil thus far measured. (See Vol. I., pp. 243-4 of this series). However, if this same aqueous solution was made 0.0015 molal with respect to CaCl_2 , the interfacial tension rose by a factor of about 3500 to 6.88 dyne cm^{-1} , an extraordinary increase.

In his early work on films of stearic and similar acids, Adam found anomalous relations, in that below 17 dyne cm^{-1} he obtained very different pressure-area relations with the three following aqueous subphases: (1) dilute HCl , (2) fresh

* Clowes, G. H. A., *J. Phys. Chem.*, 20, 408 (1916).

distilled water, and (3) old distilled water. On dilute HCl he found the ordinary "solid" phase at pressures above $17.5 \text{ dyne cm}^{-1}$, and the condensed liquid phase below this pressure. On *old* distilled water the "solid" phase alone was obtained at pressures above 2.5 dyne cm^{-1} , whereas on *fresh* distilled water the results were

FIGURE 34. Effect of time on the film pressure and surface potential of solutions of lauric acid.

the same as on HCl, except that the condensed liquid phase was found to contract rapidly.

This behavior was explained by Harkins and Myers⁶⁰ as due to metallic ions, in this case principally calcium. On HCl the film consists of stearic acid, but in old distilled water there is enough Ca^{++} ion to convert this largely into calcium stearate, which gives a condensed *solid* film at all pressures except the lowest. The fresh distilled water evidently contained a minute concentration of metallic ions (largely Ca^{++}) but not sufficient to give a solid film immediately. However, such ions gradually diffused into the monolayer and thus gradually converted a part of the stearic acid into calcium stearate. Since at 25°C the extrapolated area for the liquid monolayer is 24.40 \AA^2 (24.38 by Harkins and Copeland, and 24.41 by Nutting

and Harkins) and for the solid monolayer is 20.3 \AA^2 , the area per hydrocarbon chain is 16.8 per cent less for the calcium salt than from the acid. (Fig. 35a).

These last results are taken from the unpublished work of Harkins, Copeland, and Adinoff. The values for the calcium stearate film were obtained on a subphase of NaHCO_3 solution with a pH of 8.0. Above the transition pressure of 25.5 dyne

FIGURE 35a. Ca^{++} ions in a basic subphase transform the liquid condensed (L_c) film (dots) into a solid film (solid line).

cm^{-1} the acid and its calcium salt give practically the same area per chain at the same pressure. Thus the Ca^{++} ions do not seem to pack the chains more or less tightly, but at pressures below 25.5 dyne cm^{-1} they transform the less condensed liquid phase into the more condensed solid phase. At a pH of 7.6 with 10^{-4} molar Ca^{++} ions, remarkable time effects were observed. (Figs. 35b and c).

According to one theory developed by Harkins the change of phase produced by Ca^{++} ions may be attributed to their coordination number of 8. It is assumed that each Ca^{++} ion in the film is attached to four $-\text{COO}-$ ions of the long-chain acid, and to four water molecules of the subphase. Since each $-\text{COO}-$ ion is attached to two different Ca^{++} ions, this gives the proper ratio of one Ca^{++} ion to two $-\text{COO}-$ ions. Another point of view also advanced by the writer is that the calcium stearate

FIGURE 35b. Film pressure vs time.

FIGURE 35c. Film pressure vs reciprocal of the time.

is insoluble and forms a solid monomolecular sheet in which two stearate ions are combined with one calcium ion.

Monolayers of this type exhibit considerable rigidity and may be classed as truly solid.

According to Langmuir and Schaefer,* the monolayer on a subphase of 10^{-4} molal calcium carbonate is the nearly neutral soap at pH 11, but at pH 5.1 is one-half neutral soap, while it consists entirely of the free fatty soap at pH 3, which is quite far on the acid side of the neutral point.

Mitchell, Rideal, and Schulman find that in the photochemical decomposition of α -hydroxy-stearic acid on a 0.01*N* sulfuric acid subphase, probably with the splitting off of carbon dioxide, the reaction occurs only if the wave length is below 2400 Å, but that 3γ of nickel ions per 500 cm^{-3} sensitizes the reaction to light of 2537 Å. Also A. H. Hughes found that even in 0.01*N* hydrochloric acid ferric ions affect both the surface potential and the physical state of the film. On the same subphase the surface potential of a stearic acid monolayer is increased from 50 to 60 mv by ferric ions at concentrations greater than 0.0002 molal; but copper, nickel, cobalt, chromic, or ferrous ions produced no such effects at $M/300$.

MIXED MONOLAYERS

Introduction

Mixed monolayers on an aqueous subsolution exhibit a certain analogy in two dimensions to solutions and mixed crystals in three dimensions. Thus at fixed values of temperature and film pressure, a component of the film may possess a certain definite solubility in the monolayer.

The properties of mixed films, that is, those which consist of two or more components in addition to water, are of fundamental importance for biology, since membranes are undoubtedly structures built up on one or more mixed monolayers as a foundation. Indeed, the first investigation of mixed films was undertaken by Leathes† on account of the supposed importance in biology of monolayers of this type; but it seems preferable to consider the behavior of simpler molecules, such as the mixtures of alcohols and acids investigated in 1925 by Harkins and Morgan.²⁵ However, before this is done it is desirable to give a few of the relations exhibited by monolayers in which nonpolar molecules are mixed with those which are polar-nonpolar.

Solubility of Nonpolar Oils in Expanded Monolayers of Polar-Nonpolar Substances

The attraction between a nonpolar oil and water is due largely to dispersion forces, whose energy varies inversely as the sixth power of the distance. Polar groups exhibit an energy which varies as the inverse cube, and also with the cosine of the angle between the dipoles.

In the case of alcohols, organic acids, or amines, hydrogen bonds increase the attraction between the monolayer and water, or in the monolayer itself. These are highly directional bonds of low energy when compared with covalent bonds.

On account of its relatively low attraction for water, a nonpolar oil should not be able to remain in a liquid condensed monolayer of an acid, alcohol, etc.; but in a liquid expanded monolayer at low film pressure (and high area) there is area between molecules which is not completely occupied, and which is therefore available for occupation by molecules of nonpolar oils. Thus it is not surprising that, as found by Harkins and Myers,^{56, 59} the shape of the pressure (π)—area (σ) curves for myristic, pentadecylic, and similar acids is greatly changed by the presence of a non-volatile hydrocarbon, such as Nujol (Fig. 36). Small amounts of Nujol increase the film

* Langmuir, I. and Schaefer, V. J., *J. Am. Chem. Soc.*, **58**, 287 (1936).

† Leathes *Z. Physiol. Chem.*, **130**, 113 (1923); *Lancet*, ii, 853 (1925).

pressure at all areas; large amounts decrease the film pressure at the lower areas. It may be noted that at a very low film pressure the presence of Nujol increases the area per molecule of *acid* from the standard value of 46 \AA^2 to about 56 \AA^2 with myristic or 53 \AA^2 with pentadecylic acid. With some proportions the areas are intermediate.

FIGURE 36. Mixed monolayers of pentadecylic acid and a hydrocarbon oil (Nujol).

It is of interest that a sufficiently large proportion of nonpolar oil, which is partly dissolved in the monolayer, and partly present as lenses on top of the monolayer, removes the second-order transition between the expanded and the intermediate states.

That the monolayer of acid dissolves hydrocarbon was shown by the use of an ultramicroscopic examination⁶⁴ of the monolayer. At 23°C a myristic acid monolayer which contained 35 per cent of the hydrocarbon oil was found to be optically empty at a very low film pressure, which shows that this much of the oil is soluble in the monolayer. At a film pressure of 5 dyne cm^{-1} the solubility was reduced to 25 per cent, and at $13.5 \text{ dyne cm}^{-1}$ to 9.2 per cent (Fig. 37a). When the solubility was obtained by compressing the film it was found that too rapid compression appeared to give a slight supersaturation.

The phenomenon is an extremely beautiful one as observed in the ultramicroscope. If the film is "clean" the field is found to be almost optically empty; but when a slight supersaturation is obtained, a great number of brilliant scintillating droplets suddenly appear. These disappear just as suddenly if the area is increased slightly, and this procedure may be repeated as often as desired. The pressure-temperature and molecular area at this point give the values under which the solubility is represented by the composition of the film.

FIGURE 37a. Determination of Solubility in Two-dimensional Systems by the Ultramicroscope.

The Squeezing out of Crooked Molecules from Monolayers by Increase of Pressure: Separation of Oleic Acid from Monolayers of Stearic Acid, Stearyl Amine, etc.

Mixtures of oleic acid with cetyl alcohol, tripalmitin, and triolein have been investigated by Schulman,* who found that in every case the film was unstable above the collapse pressure of the component which has the lower collapse pressure.

Ultramicroscopic investigations on mixed films of this type by Florence and Harkins⁷³ have revealed extremely interesting relations, as follows:

(1) On an acid subphase at pH 3, oleic acid separated from a monolayer of either stearic acid or stearyl alcohol as visible lenses at a mean molecular area of 22.5 \AA^2 on increase of film pressure to 24 dyne cm^{-1} . In these films half the molecules were of oleic acid and half were of the other constituent (Fig. 37b).

(2) After the lenses appeared, the film pressure increased much more slowly as the oleic acid separated, until at about 27 dyne cm^{-1} and a mean area of all of the molecules of 10.5 \AA^2 , the pressure began to rise rapidly. It is evident that here practically all the oleic acid has been squeezed out of the monolayer, and that the stearic acid or stearyl alcohol which remains has a molecular area of $10.5 \times 2 = 21 \text{ \AA}^2$. The linear pressure-area plot above this pressure is, for the alcohol, almost exactly that for the pure alcohol, although a trace of oleic acid may remain until the film pressure rises to 40 dyne cm^{-1} . The monolayer of stearic acid alone is not so stable and collapses at 32 dyne cm^{-1} .

If oleic acid is replaced by elaidic acid, lenses appear at about 24 dyne cm^{-1} if the other constituent is either stearyl alcohol or stearic acid, but the amount of elaidic acid which separates as lenses is *very small* (see Fig. 38), as is made evident by the fact that for the equimolar mixture at about 25°C the mean molecular area is 19.5 \AA^2 .

* Schulman, J. H., *J. Biochem.*, **29**, 1243 (1935).

FIGURE 37b. Pressure-area relations of an oleic acid monolayer, and of mixtures of oleic acid (HOL) with stearyl alcohol (StOH), stearic acid (HSt), and stearyl amine (StNH₂) on a sub-solution of pH 3. The arrows represent the points at which lenses of oleic acid become visible in the ultramicroscope. Since at the extreme left all of the oleic acid has been squeezed out the figure has been drawn in such a way that the values of the area multiplied by two give the areas for the constituent left in the film: *e.g.*, the almost vertical line at 10.5 Å² for the mixture of oleic acid and stearyl alcohol indicates that the molecular area for the alcohol left alone in the film is 21 Å².

FIGURE 38. Same as Fig. 37b but oleic acid, the *cis* form replaced by elaidic acid, the *trans* form.

at 40 dyne cm^{-1} for the mixture of stearyl alcohol and elaidic acid. At this temperature and pressure the alcohol alone exhibits an area of 20.0 \AA^2 , which is not much higher.

The explanation of the fact that at the higher pressures almost all the elaidic acid molecules remain in these mixed films, while the oleic acid molecules are squeezed out (to form lenses on top of the film) is extremely interesting. Oleic and elaidic acids are space isomers with a double bond in the middle of the hydrocarbon chain. Since oleic acid is the *cis* isomer it has a much greater bend at the double bond than elaidic acid, which is in the *trans* form (Fig. 39). Thus when the orientation

FIGURE 39. Arrangement of carbon atoms in *cis* and *trans* arrangements at the double bond.

of the molecules is approximately perpendicular to the surface of the water, an oleic acid molecule occupies more area than one of elaidic acid, and this in turn more than one of stearic acid, stearyl alcohol, etc. Since the energy of attraction between the chains varies inversely as the sixth power of the distance, oleic acid molecules are very much less tightly bound in the monolayer than the others. Since all the three acids have carboxyl groups adjacent to the water, it is not to be expected that the oleic acid can be less tightly bound to the water than the others.

Penetration of Insoluble Monolayers of Alcohols and Biological Derivatives by Capillary-active Substances (Fig. 40)

An interesting observation made by Schulman and Hughes* shows that great changes in the film pressure and potential of an insoluble monolayer may be produced by injecting beneath it certain capillary-active substances. Schulman and

* Schulman, J. H., and Hughes, *Proc. Roy. Soc., London* **A124**, 333 (1929).

Stenhagen* consider that the phenomenon is due to the formation of definite compounds: for example, that one molecule of cetyl alcohol combines with either one or three, but not with two, molecules of sodium cetyl sulfate, when an insoluble film of the alcohol is penetrated by the latter. However, the recent unpublished work of Harkins, Gordon, and Copeland, and the earlier work of Harkins and Florence, show that the *evidence* presented for the existence of these compounds is not correct, as will be shown later.

FIGURE 40. Pressure-area relations of equilibrium of monolayers of cetyl alcohol after penetration of molecules of sodium cetyl sulfate from aqueous solution of molal concentrations: 3×10^{-6} ; 1×10^{-5} ; and 3×10^{-5} at 25°C . Harkins, Gordon, and Copeland, with dotted curve by Schulman at $1 \times 10^{-5} \text{ m}$ for comparison. Schulman's values do not represent equilibrium, but only "one minute points."

The qualitative results of Schulman and co-workers indicate that the effects are highly specific: "for instance, saponin readily penetrates films of cholesterol or ergosterol, but not films of cholesterol acetate, cetyl alcohol, or calciferol. Similarly sodium cetyl sulfate penetrates cholesterol films, but not those of cholesterol acetate or calciferol."

The fact that sodium cetyl sulfate will penetrate monolayers of cetyl or elaidyl alcohol, but not readily one of oleyl alcohol, is due to the considerable bend in the latter molecule due to the *cis* form at the double bond. This indicates that London dispersion forces play a part in this phenomenon.

The change in the pressure-area relations at 25°C of a monolayer of cetyl alcohol, as produced by different concentrations of sodium cetyl sulfate, is illustrated by Fig. 40, taken from the work of Harkins, Gordon, and Copeland. The curve on the left is for a monolayer of cetyl alcohol, which at 25°C and 26 dyne cm^{-1} gives an area of $20.3 \text{ Å}^2 \text{ molecule}^{-1}$. The first curve to the right of this exhibits the *equilibrium* relations when the aqueous subphase contains 3×10^{-6} mole of sodium cetyl sulfate per 1000 g water. The effect of the penetration by this latter substance is to increase the area per molecule of cetyl alcohol, plotted on the *x*-axis very slightly at high pressures. At low pressures and above 50 Å^2 per molecule of alcohol,

* Schulman, J. H. and Stenhagen, E., *Ibid.*, **B126**, 356 (1938).

the film pressure differs only very slightly from that given by the sodium cetyl sulfate alone ($6.46 \text{ dyne cm}^{-1}$). However, at an area of 26.7 \AA^2 for the alcohol, the pressure alcohol when alone is not far from 20 \AA^2 , and since if sodium cetyl sulfate had an area of 20 \AA^2 , the area 40 \AA^2 would correspond to the molecular area of the 1:1 compound, Schulman concludes that since 38 \AA^2 is close to 40 \AA^2 , the cause of the collapse at this area is the existence of this definite compound. However, since our work indicates that at a film pressure of 50 dyne cm^{-1} there is a continuous change of area from 20 \AA^2 to more than 35 \AA^2 per molecule of alcohol, if equilibrium is attained, his evidence is worthless, since it does not correspond to the facts. His evidence that a compound of 1 alcohol: 3 sodium cetyl sulfate exists is based on a kink at about 78 \AA^2 , which is close to 80 \AA^2 , which would allow area for a 1:3 compound, provided the proper area for the sodium sulfate molecule is 20 \AA^2 . However, since accurate work reveals no such kink, there is no evidence for this compound. This does not prove that compounds do not exist, but only that there is no *evidence* for their existence.

The curve which represents the penetration from a 10^{-5} molal solution of sodium cetyl sulfate gives an opportunity to compare this work with that of Schulman, whose curve for the same concentration is shown by the dotted line. The great difference between the two is due to the fact that Schulman used a single film, whose area was decreased each 60 seconds (1-minute points); thus time was not allowed to attain equilibrium by diffusion from the film into the subphase. In our work each point plotted represents a separate experiment. At an area of 45 \AA^2 per molecule of sodium cetyl sulfate, the film pressure was still changing slowly at the end of six hours when 10^{-5} molal sodium sulfate was used. With 3×10^{-6} molal sodium cetyl sulfate equilibrium was attained more slowly.

On account of the long period needed to attain equilibrium, experiments of this type should be carried out with great care. For this work the highly accurate thermostat of Harkins and Copeland (see Fig. 21) was used. In this the trough and film balance are totally inclosed by a thermostat filled with aqueous diethylene glycol, regulated to 0.001° C . The air in the thermostat is kept very nearly saturated with water vapor. The vertical type of film balance was used. The film pressures, which for a single point were taken for periods as long as 12 hours or even more, were recorded automatically on the photographic film of a motion-picture camera by a method devised and an apparatus constructed by Gordon. The mirror of the film balance gave a fine line of light on a very long vertical Celluloid scale, graduated in millimeters. The mechanical device, operated by a synchronous clock, causes the motion-picture camera to take a photograph of the scale every five minutes during the whole time necessary to attain equilibrium.

From other work in this laboratory it has been found that these mixed films may give pressures as high as about 60 dyne cm^{-1} , but a peculiar phenomenon prevents the measurement of these high pressures in the ordinary type of experiment. This is because at about 50 dyne cm^{-1} these solutions begin to spread over the paraffin used to keep the aqueous phase from spilling over the edge of the trough.

For this type of work a new technique was developed six years ago. Instead of injecting the solution of the surface-active material under the insoluble monolayer, which leads to an inhomogeneous solution and monolayer, the first step is to fill the trough with a homogeneous solution. For example, the trough is filled with a solution of sodium cetyl sulfate. On the surface of this solution two barriers are placed in contact with each other, and perpendicular to the length of the trough. One of these is moved rapidly away from the other, thus sweeping off the adsorbed monolayer of sodium cetyl sulfate. As the moving barrier advances, drops of a hexane solution of cetyl alcohol, or another film-forming substance, are put on the surface just behind this barrier. Since the film pressure of the alcohol is greater than that of the sodium cetyl sulfate, the surface of the water is covered by the

insoluble film before appreciable penetration occurs. This technique leads to the formation of a homogeneous mixed film.

Mixtures of Components Each of Which Gives a Condensed Film (Fig. 41)

The following interesting relations are exhibited by the film which consists of an equimolar mixture of stearic acid and octadecyl (stearyl) alcohol.⁷²

(1) The liquid condensed film exhibits a molecular area which is the mean of that given by the pure components. Thus the "limiting areas at zero pressure" as obtained by extrapolation are at 25° C: stearic acid = 24.3, octadecyl alcohol = 21.9, mean value calculated = 20.1, determined = 23.1.

(2) The S or "solid" film, has almost exactly the same molecular area in films of either the acid or the alcohol, but for the equimolar mixture the area is higher (by

FIGURE 41. Pressure-area relations of mixtures of stearic acid and stearyl alcohol.

about 0.75 \AA^2). This seems to be due to the fact that the transition $L_e \rightleftharpoons S$ occurs in the mixture at a pressure which is much (1.4 dynes) below the mean of the kink points for the films of one component. If S films were to be considered as two-dimensional solids, then it could be said that the mixed film freezes at a larger molecular area than that of either component.

The Condensing Effect of Alcohols upon the Expanded Monolayers of Acids

Alcohols with 14 or more carbon atoms per molecule form highly condensed S films at high and liquid-condensed films at low pressures. These substances reduce greatly the extent of the expansion in liquid-expanded and intermediate films. However, they may exhibit an area either higher (+) or lower (−) than the mean value, and in Table 11 this is represented as the interaction in \AA^2 at the limiting area for the film. This is the area at which the pressure begins to rise rapidly above that of the two-dimensional vapor from the film.

In both Table 11 and Figs. 42 and 43 the numbers in the first column or on the curve represent the number of carbon atoms in the hydrocarbon chain, first of the alcohol and secondly of the acid. Thus 18–15 represents a mixture of octadecyl alcohol and pentadecylic acid. As compared with the mean value the relations which are obtained may be noted as follows:

- (1) A contraction occurs if in mixtures with pentadecylic acid the alcohol chain is of the same length or longer than that of the acid.

FIGURE 42. Mixtures (1:1) of condensed alcohol and expanded films of pentadecylic acid. Pentadecylic alcohol eliminates the expanded film of pentadecylic, but not that of myristic acid. The first number gives the number of carbon atoms in the molecule of alcohol, and the second, in the acid.

FIGURE 43. Mixtures (1:1) of condensed alcohol films and expanded films of myristic acid (pH = 3). The curve for myristyl alcohol with pentadecylic (acid 14-14) is added for comparison with the effect produced with interchange of number of carbon atoms in the alcohol and acid). Stearyl alcohol does not condense the myristic acid, while it does the pentadecylic acid film (Figure 42).

Table 11. Increase of Area or of Surface Potential (Interaction) Above the Mean Value for Mixtures of Acids, Alcohols, and Amines

- (2) Expansion is exhibited if the alcohol chain is the shorter.
- (3) With myristic acid there is contraction if the alcohol chain is much longer (*i.e.* 18–14) but expansion if the alcohol chain is one atom longer or of the same length.

It is of considerable interest that in an equimolecular mixture any alcohol of greater length than 14 carbon atoms eliminates the expanded film and leaves only the intermediate film (15–15, Fig. 42) or the liquid condensed film (18–15). That is, the transition pressure ($I \rightarrow L_c$) or kink, is depressed to negative film pressures.

It is found (Fig. 43) that equimolecular mixtures of the 14 alcohol with 15 acid, and of 15 alcohol with 14 acid, give the same pressure-area curve for the transition film over a considerable region, but the expanded liquid film exhibits a considerably higher pressure if the acid chain is the longer.

With myristic acid, stearyl alcohol inhibits the expanded film, but pentadecyl alcohol permits its existence.

Since the molecular interaction is expressed in \AA^2 at the limiting area, it is not surprising that there is an expansion with reference to the mean when the mixed film at this area is an expanded one, and a contraction when the film is of either the L_c or the I type.

If the mixed film is of the intermediate type and that of the acid expanded, the relation is reversed. Thus at 7 dynes the interaction is -6.2 \AA^2 for the 14–15 mixture while it is $+7.1$ at the limiting area.

Thus the sign and magnitude of the interaction depends upon the effect of the mixing upon the state or class of the film which is produced.

Increasing the chain length of the condensing agent has the same effect as a lowering of temperature even though this effect is not apparent with the pure alcohols with from 14 to 18 carbon atoms. Increasing the chain length of the expanded acid has a similar effect.

The deviation from the mean of the surface potential for the alcohol-acid monolayers is positive in all cases, and is smallest in magnitude when the difference in chain length is greatest. The greatest interaction in mv is 63 for the 15 alcohol–14 acid, and 50 for the 15–15 mixture. These are the largest interactions as measured by the potentials.

Films of Mixed Acids

Films of mixed acids (Fig. 44) exhibit the same general relations as those which consist of an acid and an alcohol, except that a long chain acid condenses an expanded film of an acid much less than the alcohol with the same number of carbon atoms. For example, at an area of 26 \AA^2 the equimolecular mixture of the 18 and 14 acids gives a film pressure of 8.5 dynes/cm, while with the 18 alcohol and the 14 acid it is only 3.3 dynes. This is related to the fact that liquid condensed alcohol films are much more condensed than those of the same type with acids.

One component films of arachidic (20) or stearic (18) acid exhibit practically the same pressure-area relations for the liquid film, and when mixed in equimolecular proportions with myristic acid give almost the same values. In the case of the mixtures the interaction in terms of the surface potential is negative (Table 11), which is the opposite sign from that for alcohol-acid mixtures.

In mixtures of the 22–14 acids Adam and Jessop* were unable to detect an appreciable condensation but in this work the mixture gave an increase from the mean of 2.5 \AA^2 at the limiting area, but only 0.25 \AA^2 at 8 dynes per cm. These involve comparisons of expanded films for the pure 14-component and the mixture. At 12 dynes the condensation is 6.3 \AA^2 , but here the mixture is in the intermediate state. These facts indicate that for an understanding of the relations between the films

* Adam, N. K., and Jessop, G., *Proc. Roy. Soc., London* **A120**, 473 (1928).

FIGURE 44. Mixtures of condensed and expanded acid films ($\text{pH} = 3$). Arachidic, stearic, pentadecylic, and myristic acids. The pressure-area values for the 20-14 and 18-14 mixtures are almost the same, but the position of the transition point expanded transition ($L_e \rightarrow I$) is affected by an extremely large shift.

of pure components and the mixtures in all of this work it is essential to study the entire curves as presented in the figures.

Positive Organic Ions in Mixed Films

Alcohol-Amine Mixtures: The use of amines on dilute acid subsolutions gives an opportunity to investigate the effect of a positive ion of an organic type. In alcohol mixtures this gives rise to an ion-dipole effect. The pure amines on acids give vapor-expanded films of extremely high expansion, but these are very greatly condensed by the addition of an equal number of molecules of the 14 to 18 alcohols (Fig. 45). Of the mixtures, that in which both the amine and the alcohol have 18 carbon atoms gives the closest approach to a solid film, with an extrapolated area at zero compression of 20.7 \AA^2 which is the normal value for solid condensed films. All of the other mixtures give curves of the general type exhibited by intermediate films.

At the low pressure of the limiting area the 14 alcohol and the 18 amine give the highest, and the 18-18 mixture the lowest area, as might have been predicted, but at the higher pressures the order is shifted on account of the fact that the 14-16 mixture is by far the most compressible, as is normal.

Mixtures which contain the 16 carbon amine not only give abnormally low areas at the high pressures, but they also exhibit extremely high positive deviations (ΔV) of the surface potential from the mean values. Thus (Table 11) the interaction was +200 mv for the 18-16, 100 mv for the 16-16, and 200 mv for the 14-16 mixture, if the first number of each pair refers to the alcohol and the second to the amine. The mixtures with octadecyl- (stearyl-) amine give potential deviations of the same sign and order of magnitude as those found with the alcohol-acid mixtures, that is 25 to 60 mv. The large deviations with cetyl amine as listed above were the maxima, and it is not certain that the films were molecularly homogeneous.

The effect of changing the proportions in the alcohol-amine mixtures is exhibited

FIGURE 45. Mixtures (1:1) of condensed alcohol and vapor-expanded amine films ($\text{pH} = 3$). For the one-component alcohol films see Fig. 42 and Fig. 43. The curves at the lower pressures are of the transition type. The first number gives the number of carbon atoms in the alcohol, and the second in the amine, molecule. The 14-16 and 18-16 mixtures have a high compressibility.

FIGURE 46. Effect of proportions in mixed stearyl alcohol and amine films ($\text{pH} = 3$). The first figure gives the number of molecules of amine and the second of alcohol. The 1:1 mixture exhibits the greatest condensation.

in Fig. 46. It may be noted that the 1:1 mixture gives the lowest area, and that one molecule of stearyl alcohol to two of the stearyl amine was not sufficient to give a solid film, though in Fig. 45 it has been shown that 1:1 produces the transformation.

Acid-Amine Mixtures ($\text{pH} = 3$): When an organic acid is present in the mixture there is the possibility of a chemical action with the positive ion of the amine, so an even more powerful condensing action is to be expected. Thus it is not surprising that a mixture of myristic acid with either cetyl or stearyl amine, both of which when alone form very highly expanded films at 25°C , gives a highly condensed film, but in no case is the relation between film pressure and molecular area linear (Fig. 47). The positive deviation of the surface potential from the mean is very high (Table 11), of the order of 200 mv, and is highest for the equimolar mixture.

FIGURE 47. Mixtures (1:1) of acids and amines ($\text{pH} = 3$). The first figure gives the number of carbon atoms in the acid, and the second in the amine, molecule. All of the seven mixtures exhibit pressure-area curves of the same form, and with not very widely differing and very low areas. At the lower pressure all the mixtures give curves of the transition form.

In the acid-amine mixtures examined, 14-18, 15-18, 16-18, 18-18, 14-16, 16-16, 18-16, there is no evidence of a definite effect of chain length. All of the curves for the mixtures are seen to be practically parallel, and of the same form, and the difference in area is not very significant.

The effect of a change of the relative proportions of stearyl amine and stearic acid is presented in Fig. 48, where for example 4:1 means 4 molecules of amine to one of acid. The 1:1 mixture is found to give the minimum area and the greatest interaction of the potentials (200 mv).

The pressure of the transition $L \rightleftharpoons S$ for the mixtures is lowered, as the proportion of the amine is increased, from 25 dynes/cm for the pure acid, to 15.4 for one-seventh amine, to 9.8 for one-fourth amine, and the transition point disappears for two-fifths amine or more.

The effect of changes of the proportions in a mixed film of stearic acid and

In general, changes of phase in two dimensional condensed systems involve no heat change. The energy of expansion is related in a remarkable way to the nature of the phase of the monolayer. Its magnitude and its variation with changes in phases or transitions between them, give important knowledge of the molecular interactions in two dimensional systems, and may be used to test the validity of theories of the molecular structure of the monolayer.

As an example of this we may test a well-known theory of the structure of a monolayer in the intermediate phase as proposed by Langmuir. Consider this phase as having just been formed by a transition from a liquid expanded phase by decrease of area. According to the theory the molecular structure is the same as in the expanded phase, except that a few micelles have now formed. With a given film forming substance every micelle contains the same small number (*e.g.*, 13) of molecules. This makes it essential that if in the expansion of the monolayer a certain micelle begins to dissociate, it must disappear completely, as an aggregate, before another micelle begins to disintegrate. Since the molecular area in the micelle is much less than that in the nonmicellular material, this phase should have a very high compressibility, as is true. However, Langmuir's theory predicts that, as the intermediate phase is compressed, the energy of compression should remain constant.

The measurements show, however, that for a normal long chain paraffin acid this energy is about 300 ergs per sq cm during the early part of the compression, but decreases gradually to zero before this phase changes into a liquid condensed phase. Thus if the micelle theory is to correspond with these facts the micelles would need to vary in size with the compression, instead of remaining of constant size. According to Kirkwood's theory, the structure is very different.

While a three-dimensional gaseous or condensed phase has only a single isothermal energy of expansion, this is not true of a monolayer. Consider a rectangular monolayer which is confined at one end of a rectangular trough by a single transverse barrier. If the barrier is moved in such a way as to (1) increase the area of the film by one cm^2 and to decrease the area of the water by the same amount the energy required is h_s , the energy of spreading of the monolayer. If, however, a ring or any other object in contact with the film is raised far enough to increase the area of the film by 1 cm^2 without affecting the area of the clean water, the energy required is designated by h_e , the energy of *extension* of the monolayer.

It is evident that $h_e = h_s - h_w$, since in spreading the energy of the film is increased by h_s , but the energy of the surface of the water is decreased by h_w , since unit area of the water disappears.

In other words the energy of extension of a monolayer is always greater than the energy of spreading by an amount equal to the surface energy of water at the given temperature. At 25°C this is $118.5 \text{ erg cm}^{-2}$.

Determination of the Energy of Spreading (h_s) and of Extension (h_e)

A monolayer of pentadecylic acid at a temperature of 20°C and a molecular area of 34.3 \AA^2 per molecule has a film pressure (π) of 3 dyne cm^{-1} , so the surface tension of water covered by the film is $72.75 - 3 = 69.75 \text{ dyne cm}^{-1} = \gamma_f$. Here $72.75 \text{ dyne cm}^{-1}$ is the surface tension of clean water. If the film is of infinite extent its face energy is increased by $69.75 \text{ erg cm}^{-2}$ if the area is increased by one cm^2 . The film is being thus extended absorbs an amount of heat

$$q_e = -T \left(\frac{\partial \gamma_f}{\partial T} \right)_\sigma = T s_e = 293 \times 1.106 = 324 \text{ erg cm}^{-2}$$

The total energy required for extension of the film is therefore:

$$h_e = \gamma_f - T \left(\frac{\partial \gamma_f}{\partial T} \right)_\sigma = 69.75 + 324 = 394 \text{ erg cm}^{-2} \quad (34)$$

If the energy of spreading (h_s) is desired, it is only necessary to subtract from each of these values the corresponding value for clean water. Thus

$$\begin{aligned} f_s &= \Delta\gamma_s = \gamma_s - \gamma_w = 69.75 - 72.75 = -3.0 \text{ erg cm}^{-2} \\ s_s &= s_s - s_w = 1.106 - 0.148 = 0.958 \text{ erg cm}^{-2} \text{ deg}^{-1} \\ h_s &= h_s - h_w = 394 - 116 = 278 \text{ erg cm}^{-2} \\ \gamma_s &= \gamma_s - \gamma_w = 324 - 43 = 281 \text{ erg cm}^{-2} \end{aligned}$$

These and other values are listed in Tables 12a and b.

The experimental determination of these energy quantities for an insoluble film is very simple. The surface tension of the film is simply the surface tension of water (γ_w) minus the film pressure (π). The other quantity needed is the rate of change of the surface tension of the film, at constant area, with the pressure. This rate of change is the slope of the curve which relates film pressure to temperature, as in Fig. 49, which represents the intermediate phase (steep curves) and the liquid expanded phase (1.), with a more gentle slope, at higher values of π and T .

The energy changes in the expansion of a monolayer on water are remarkable in their variation with the phase involved, as indicated by the values in Table 13, which gives only the order of magnitude of the various energies (See Figs. 49b, c, and d).

THERMODYNAMICS OF THE SPREADING OF FILMS ^{21, 35, 81, 83}

The maximum work (δW) done by a surface when its area (σ) is increased by $d\sigma$ is

$$\delta W = -\gamma d\sigma + p dv. \quad (35)$$

The value of the free energy of Gibbs is defined by the equation

$$F = E - ST + pv \quad (36)$$

and the Helmholtz free energy by

$$A = E - ST. \quad (37)$$

FIGURE 49a. Pressure-temperature relations of monolayers of myristic and pentadecylic acids. From left to right: L_e , I , and L_e phases. The upper part of the highest curve for myristic acid has a slope of incorrect sign, since at this high temperatures and pressures myristic acid monolayers are slightly soluble.

FIGURE 49b. Pressure temperature relations of palmitic acid monolayers (condensed and intermediate phases).

FIGURE 49c. Pressure-temperature relations of pentadecylic acid.

FIGURE 49d. Increase of the "Heat Content" for spreading $h_s = (\partial H_s / \partial T)_{p,T,\sigma}$ as a function of temperature and pressure; numbers on curves give the film pressure π .

It follows that

$$F = A + pv \tag{38}$$

and

$$dF = dA + p dv + v dp. \tag{39}$$

If a processes is reversible and isothermal, $T\Delta S = Q$ is the heat adsorbed and

$$dA = -dW, \tag{40}$$

so

$$dF = -dW + p dv + v dp. \tag{41}$$

From (41) and (35)

$$dF = \gamma d\sigma + v dp, \tag{42}$$

so that at constant pressure and temperature

$$(\partial F / \partial \sigma)_{p,T} = \gamma \tag{43}$$

and for a saturated surface γ is a function of p and T only, so

$$\Delta F = \gamma \Delta \sigma, \tag{44}$$

$$f = \gamma. \tag{45}$$

The condition that a liquid b shall by itself spread on a liquid a , at constant temperature, is thus that the summation of the terms $(\partial F/\partial \sigma')_{p, T}$ must be negative, that is less than zero. Thus, if b spreads on a , a certain area of the surface of a disappears and certain areas of the surface of b and of the interface ab , appear. The increase of free energy is

$$dF = \left(\frac{\partial F}{\partial \sigma_b} \right)_{p, T} d\sigma_b + \left(\frac{\partial F}{\partial \sigma_{ab}} \right)_{p, T} d\sigma_{ab} + \left(\frac{\partial F}{\partial \sigma_a} \right)_{p, T} d\sigma_a. \quad (46)$$

For a film of appreciable thickness the effects of gravitation must also be considered; but they may be neglected here.

The condition for spreading to occur starting from any given condition, is

$$dF < 0, \quad (47)$$

and for non-spreading

$$dF > 0. \quad (48)$$

If it is assumed that

$$d\sigma_b = d\sigma_{ab} = -d\sigma_a, \quad (49)$$

which is practically valid for a very thin layer, then

$$(dF/d\sigma)_{p, T} = \gamma_b + \gamma_{ab} - \gamma_a. \quad (50)$$

provided the film is *duplex*, that is, thick enough to cause the film of b to exhibit the surface tension of the pure liquid. Let $-dF/d\sigma$ be designated as the final spreading coefficient ($S_{b/a}'$) then

$$S_{b/a}' = \gamma_a' - (\gamma_b' + \gamma_{ab}'). \quad (51)$$

($p, T = \text{constant}$, the surfaces are saturated as is designated by the primes). It will be shown later that

$$S_{b/a}' < 0. \quad (52)$$

That is, the final spreading coefficient is always negative.

Now if a drop of the *pure* liquid b is put on the surface of the pure liquid a , and the surfaces of these liquids are considered to be still uncontaminated with each other, then the initial coefficient of spreading $S_{b/a}$ is given* by the equation

$$-(dF/d\sigma)_{p, T} = S_{b/a} = \gamma_a - (\gamma_b + \gamma_{ab}). \quad (53)$$

If b is saturated with a , but the surface of a is clean, the initial coefficient may be designated as the semi-initial spreading coefficient ($S_{b/a}'$), which, on account of the small effect of water on the surface tension of an organic liquid, is not very different from $S_{b/a}$ when these are the liquids involved.

Now

$$S_{b/a}' = \gamma_a - (\gamma_b' + \gamma_{ab}'). \quad (54)$$

The work (W_A) required at constant T and p to pull the interface ab apart to give clean surfaces of a and b , is, for unit area of interface, given by:

$$W_A = \gamma_a + \gamma_b - \gamma_{ab} \quad (55)$$

and the work of cohesion (W_c) for the liquid b is*

$$W_{cb} = 2\gamma_b \quad (56)$$

or

$$W_A - W_{cb} = \gamma_a - (\gamma_b + \gamma_{ab}). \quad (57)$$

* W. D. Harkins and A. Feldman, *J. Am. Chem. Soc.*, **44**, 2665 (1922); W. D. Harkins, *Sixth Colloid Symposium Monograph* (1928), p. 31.

From (53) and (57) the initial spreading of the liquid b over the clean surface of a is given by

$$-(\partial F/\partial \sigma)_{p, T} = S_{b/a} = W_A - W_{Cb} \geq 0. \quad (58)$$

Thus spreading to form a duplex film occurs if $S_{b/a}$ is greater than zero, while b remains as a lens if it is less than zero.

TRANSFORMATION OF A DUPLEX FILM TO FORM A NON-DUPLEX THIN FILM (PRESUMABLY A MONOLAYER)

If a non-duplex thin film or a monolayer of b is present on the surface of the liquid a , the pressure (π) of the film is *defined* as:

$$\pi = \gamma_a - \gamma_f, \quad (59)$$

where γ_a is the surface tension of the pure liquid a and γ_f is its surface tension when covered with a film of b . While there is nothing in the thermodynamics which indicates that such a thin non-duplex film is always a monolayer, certain relations, presented later, seem to indicate that this is true.

What is now desired is the relation between the film pressure and the spreading coefficient, which is obtained from equations developed earlier.

In the treatment of the transformation of a duplex film into a monolayer it is essential to consider the semi-initial spreading coefficient ($S'_{b/a}$; Eq. (54)).

Equation (51) may be written

$$S_{b'/a'} = \gamma_e - (\gamma_b' + \gamma_a \gamma_b'), \quad (51')$$

where γ_e is the equilibrium value of γ_f and Eq. (54)—Eq. (51') gives

$$S_{b'/a} - S_{b'/a'} = \pi_e. \quad (60)$$

Thus π_e , the pressure of the monolayer in equilibrium with a lens of b , is equal to the semi-initial minus the final spreading coefficient.

With an oil on water the final spreading coefficient is always negative, so the film pressure (π_e) is always larger than the semi-initial coefficient ($S'_{b/a}$), which has nearly the value of the initial coefficient ($S_{b/a}$).

THERMODYNAMICS OF EXTENSION AND OF SPREADING OF A MONOLAYER

The heat content (H) of a system is given by the equation

$$H = E + pv \quad (61)$$

or

$$dH = dE + p dv + v dp, \quad (62)$$

and from 2

$$H = F + ST \quad (63)$$

or

$$dH = dF + T dS + S dT. \quad (64)$$

In the treatment which follows, energy values designated by small letters refer to the change of energy for unit area. Thus in

$$h = (\partial H/\partial \sigma)_T,$$

the h designates the increase of heat content of a film of very large area for unit increment of area.

Let us consider a trough filled with a body of water with a plane surface partly

covered with a monolayer. The area of the film together with that of the subphase may be increased by one sq cm by the use of some mechanical device while the area of the water surface is kept constant. Thus a ring of suitable dimensions, already lying in the surface, may be pulled upward until there is a unit increase of area of the film. If the film area is thus increased by $d\sigma_f$, instead of unity, the equation for the process which may be designated as *extension* (e), may be written

$$dF_e = (\partial F / \partial \sigma_f)_{T, \sigma_w} d\sigma_f = \gamma d\sigma_f \quad (65)$$

or

$$\Delta F (\Delta \sigma = 1 \text{ cm}^2) = (\partial F / \partial \sigma_f)_{T, \sigma_w} = f_e, \quad (66)$$

which gives the *free energy of extension* of the film. The entropy of extension is

$$s_e = (\partial S / \partial \sigma_f)_{T, \sigma_w} = -(\partial \gamma_f / \partial T) \sigma_f. \quad (67)$$

The increment of heat content is given by

$$h_e = (\partial H / \partial \sigma_f)_{T, \sigma_w} = \left[\frac{\partial(\gamma_f/T)}{\partial(1/T)} \right]_{\sigma_f} \quad (68)$$

and the heat absorbed (q) by

$$q_e = T(\partial S / \partial \sigma_f)_{T, \sigma_w} = -T(\partial \gamma_f / \partial T) \sigma_f = Ts_e. \quad (69)$$

Similar equations may be written for the energy of *spreading* of a film. This process (s) may be assumed to occur as follows: The surface of the water in the trough is separated into two parts by a movable barrier. On one side of the barrier the surface is covered by the film, on the other side the water surface is clean. Let the barrier be moved in such a way that the area of the film is increased by 1 sq cm, and that of the water decreased by this amount.

The equations for *spreading* are:

$$dF_s = (\partial F / \partial \sigma_f)_{T, \Sigma} d\sigma_f - (\partial F / \partial \sigma_w)_{T, \Sigma} d\sigma_w = -(\gamma_w - \gamma_f) d\sigma_f = -\pi d\sigma_f, \quad (70)$$

where $\Sigma = \sigma_w + \sigma_f$.

The increase of entropy which accompanies the spreading of the film over the water is from Eq. (50):

$$s_s = (\partial S / \partial \sigma_f)_{T, \Sigma} = -(\partial^2 F / \partial T \partial \sigma_f)_{\Sigma} = -(\partial \pi / \partial T) \sigma_f, \quad (71)$$

The heat absorbed is

$$q_s = Ts_s \quad (72)$$

and the increase in heat content

$$h_s = (\partial H / \partial \sigma_f)_{T, \Sigma} = - \left[\frac{\partial(\pi/T)}{\partial(1/T)} \right]_{\sigma_f, \Sigma} \quad (73)$$

Equations (65) to (69) which give the energy and entropy of *extension* for the films are also applicable to pure liquids.

Thus using Eq. (68) Harkins calculated the increase of the heat content when the surface area of water is increased, as $h = 116$ ergs per cm^{-2} at 20° .

In Eq. (59) π is defined as

$$\pi = \gamma_w - \gamma_f, \quad (74)$$

and it can be shown that in Eq.

$$s_e = s_s + s_w \quad (75)$$

and in Eq. (67),

$$h_e = h_s + h_w. \quad (76)$$

The energy changes of the greatest interest are those associated with the isothermal expansion (or compression) of a film between any molal area σ_1 , and any other molal area σ_2 . The heat content and heat absorbed may be calculated for either the spreading or the extension of the film. For one mole of material the increase of heat content is

$$\Delta H_m = \int_{\sigma_1}^{\sigma_2} (\partial H / \partial \sigma)_T d\sigma_m = \int_{\sigma_1}^{\sigma_2} h d\sigma_m. \quad (77)$$

and the heat absorbed:

$$Q_m = T \int_{\sigma_1}^{\sigma_2} (\partial S / \partial \sigma)_T d\sigma_m = T \int_{\sigma_1}^{\sigma_2} s d\sigma_m, \quad (78)$$

where ΔH_m and h of Eq. (77) and Q_m and s of Eq. (78) stand for $(\Delta H_m)_e$, h_e , $(Q_m)_e$, and s_e when the process is one of extension, and for $(\Delta H_m)_s$, $(Q_m)_s$, and s_s when the process is one of spreading.

The heat absorbed may readily be calculated from ΔH and ΔF of any process. For *spreading*:

$$(Q_m)_s = (\Delta H_m)_s - (\Delta F_m)_s = (\Delta H_m)_s + \int_{\sigma_1}^{\sigma_2} \pi d\sigma_m. \quad (79)$$

For extension:

$$(Q_m)_e = (\Delta H_m)_e - (\Delta F_m)_e = (\Delta H_m)_e - \int_{\sigma_1}^{\sigma_2} \gamma d\sigma_m. \quad (80)$$

Table 13a. Energy of Spreading (h_s) of Two-dimensional Phases on an Aqueous Subphase at pH 2. (Values in erg cm⁻²)

| Phase | <i>n</i> -Long Chain Acids |

ENERGY RELATIONS IN TRANSFORMATIONS FROM THREE TO TWO-DIMENSIONAL SYSTEMS

Heats of Spreading and Freezing. By the application of a Clapeyron equation in the form

$$\Delta H = \lambda_{S \rightarrow F} = T \left(\frac{\partial \pi_e}{\partial T} \right) (a_F - a_S)$$

it is possible to determine the latent heat of spreading $\lambda_{S \rightarrow F}$ of a solid *S* to form a film *F* upon an aqueous subsolution. Here π_e is the film pressure at equilibrium between the crystals and the film and a the area of the surface involved. In practice a_s may be made sufficiently small to be negligible.

Since the values of the temperature required to give the same molecular area at

equilibrium in a monolayer of either the 14 or 15 carbon atom acid are not very different, it is apparent that the differences in the latent heats of spreading, at any given value of a_F , are almost entirely determined by the value $\partial\pi_e/\partial T$ of the slope of the π_e, T curve.

Values of these slopes have been determined by Cary and Rideal,* who find $\partial\pi_e/\partial T$ to be practically the same for both myristic and pentadecylic acid, that is, the π_e, T curves are parallel. The values of the latent heats of solidification or "settling" of these acids have been determined by King and Garner,† and these are, in kcal per mole, 10.7 for the even (14 C) and 10.30 for the odd (15 C) acid if the solid is in the α -form. The transformation $\alpha \rightarrow \beta$ of the odd acid evolves 1.20 kcal per mole in addition.

Thus the tightness of binding of the molecules of the even (14 C) acid may be said to be 10.7 kcal per mole greater in the crystals than in the three-dimensional liquid,

Table 13b. Latent Heat of Spreading of Myristic Acid on an Aqueous Subsolution of pH 2.0 ($\partial\pi_e/\partial T = 0.662$) ($\lambda_s \rightarrow L = 10.7$ kcal per mole)

Table 13c. Values of the Constants in the Equation

| Acid | Below a | M.P. b | Above a | M.P. -b | M.P. ($^{\circ}\text{C}$) |
|--------------|------------|-----------|------------|------------|--------------------------------|
| Myristic | 1.62 | 0.65 | 45.2 | 0.172 | 53.9 |
| Pentadecylic | 6.60 | 0.582 | 47.3 | 0.208 | 52.3 |
| Palmitic | | | 45.3 | 0.188 | 61.8 |
| Margaric | | | 42.7 | 0.137 | 60.6 |

while for the odd (15 C) acid the value is 10.3 or 11.5, as has been stated. The effects of the small changes of volume are neglected.

Energy values for myristic acid, as determined by the use of a film balance of the horizontal type are shown in Table 13b. The value of the slope $\partial\pi_e/\partial T$ was found by Harkins and Nutting to be 0.662, but later work by Harkins and Copeland by the ring method gave 0.650. That obtained by Cary and Rideal was 0.568.

Fig. 49b shows the increase of the film pressure (π_e) of the monolayer in equilibrium with crystals of palmitic acid rises rapidly with the temperature to 33.7 dyne cm^{-1} at 61.8 $^{\circ}\text{C}$, where the crystals melt, and then decreases as soon as the crystals change to liquid lenses. Below this temperature the spreading process is accompanied by absorption and above it by emission of heat.

With margaric acid the amount of heat emitted at 61 $^{\circ}\text{C}$ by spreading from a liquid lens is about 1.66 kcal mole $^{-1}$. It is obvious that the difference in sign of ΔH between crystals and lenses has its origin in the latent heat of fusion of the crystals.

INCREASE OF AREA OF A MONOLAYER DUE TO SALT IN THE SUBPHASE

That ions of a polyvalent metal in a subphase of high pH often convert the liquid condensed monolayer of a long-chain acid into a solid monolayer has been shown previously. However, this is a purely chemical effect. Harkins and Morgan²⁵

* Cary, A., and Rideal, E. W., *Proc. Roy. Soc. London*, **A109**, 328 (1925).

† King, A. M., and Garner, M. E., *J. Chem. Soc.*, 578 (1931).

FIGURE 49b. Effect of Temperature on the equilibrium pressure of crystals ($t = 44^\circ$ to 61.8° C) and of Lenses ($t = 61.8$ to 73° C) of palmitic acid.

showed in 1925 that when chemical effects are absent the effect of a salt, which increases the surface tension of water, is to increase the area of the monolayer. Phenanthrene, dibromanthracene, etc., which do not give a film on water, were found to give one on concentrated calcium chloride solution. These films were evidently monolayers studded with small three-dimensional crystals.

Since the surface tension of an 11.2 molal calcium chloride solution at 25° C is about 107 dyne cm^{-1} , or 35 dyne cm^{-1} greater than that of water, the pull on the film-covered surface by that of the clean solution is about 50 per cent greater than that of the surface of water. A very closely packed monolayer of oil reduces the surface tension of the salt solution very greatly. Thus, since

$$\pi = \gamma_s - \gamma_f$$

where γ_s is the surface tension of the salt solution, the value of π in such a case must be high.

Figure 50, from unpublished work by Harkins and Copeland, represents $M \text{ NaCl} + 0.01M \text{ HCl}$ as the subphase on a monolayer of octadecyl alcohol. This has a very much smaller effect than $11.2M \text{ CaCl}_2$, since it increases the surface tension of water by only 8.5 dyne cm^{-1} . However, it may be noted that at the lower film pressures the molecular area is about one \AA^2 , or nearly 5 per cent larger than on water. The presence of the salt was found to increase the pressure of collapse of the film to a very high value (about 61 dyne cm^{-1} , or about 250 atmospheres).

This figure shows, for the first time, three condensed phases on a single isotherm (7.42° C). The presence of the salt raises the pressure of transition, from the phase (L_c) of greatest compressibility to that with an intermediate value, from 15.7 to $20.0 \text{ dyne cm}^{-1}$, while the transition from this to the least compressible phase occurs at $45.3 \text{ dyne cm}^{-1}$.

Isotherms at 25° C for octadecylamine chloride on $10^{-2}N \text{ HCl}$ were found by Hoffmann and others (in this laboratory)* to exhibit a considerable increase of area when the subphase was made $0.01N$ with respect to HBr , and about as much again when this was replaced by HI . These relations were reversed below about 4 dyne cm^{-1} . The use of hydrogen iodide eliminated the second-order transition between the expanded and intermediate phases.

FIGURE 50. A graphic representation of M NaCl + $0.01M$ HCl as the subphase in a monolayer of octadecyl alcohol.

THE DEPOSITION OF MONOLAYERS TO FORM MULTILAYERS

It has been found by Blodgett and Langmuir* that calcium stearate and many other monolayers may be transferred from the surface of an aqueous solution to that of a solid. At certain high values of the pH of the solution the deposition on the solid occurs only on the down trip (X films), and at certain lower values on both the down and up trips (Y films), and in some instances only on the upward movement (Z films).

It is claimed by Bikerman† that strongly hydrophobic surfaces pick up monolayers on the down trip only. The relations are exhibited by him as in Fig. 51.

Blodgett and Langmuir‡ measured the thickness of multilayers by the use of

* Blodgett, K. B., *J. Am. Chem. Soc.*, **57**, 1007 (1935); Blodgett, K. B., and Langmuir, I., *Phys. Rev.*, **51**, 964 (1937).

† Bikerman, J. J., *Proc. Roy. Soc. London*, **170A**, 130 (1939).

‡ Blodgett, K. B., *Phys. Chem.*, **41**, 975 (1937); Blodgett, K. B., and Langmuir, I., *Phys. Rev.*, **55**, 391 (1939).

interference colors with polarized white light, or by interference intensities with monochromatic light. Barium stearate films were found to be 24.4 Å thick per molecular layer.

In this laboratory this method was used to determine the thicknesses of multilayers of catalase⁸³ produced by another method. Each monolayer was adsorbed

FIGURE 51. Illustrates Bikerman's theory, according to which if surface of slide is highly hydrophobic, both advancing and receding angles (between a_x or r_x and the slide) in the water are greater than 90° . If less hydrophobic the advancing angle (for a_y) is greater than 90° but the receding (up trip) is less (r_y). On withdrawing the slide deposition occurs for r_yON' but not for r_xON' , but for the down trip for both a_xON and a_yON , since all these angles are acute and allow the monolayer and the surface of the slide to approach each other during the movement of the slide. Thus the hysteresis of the contact angle is involved.

from a catalase solution upon a slide. The layers in order of their adsorption, and their mean thicknesses in Å were: (1) catalase, 53; anticatalase, 56; catalase, 10; anticatalase *ca.* 45; catalase *ca.* 10; etc. Thus catalase on anticatalase gave a thin layer, but catalase on barium stearate or anticatalase on catalase a thick one.

Porter and Wyman* found that multilayers of the Y type deposited on a slide of metal give by the method of Zisman, a very low, *almost zero*, apparent contact potential, while the potential exhibited by X multilayers is nearly proportional to the number of layers, and of the order of 60 mv per layer (See Figs. 51 to 54).

According to Langmuir's first idea, this potential was supposed to be due to the dipoles of the molecules of the multilayer. Later he and Harkins and Matton† attributed the apparent contact potential to the presence of charges.

Charge Theory of Multilayer Potentials^{68, 75}

The theory of these potentials, as developed by Harkins and Mattoon, is given below.

* Porter, E. F., and Wyman, P., *J. Am. Chem. Soc.*, **59**, 2746 (1937); **60**, 1083 (1938).

† Langmuir, I., *J. Am. Chem. Soc.*, **60**, 1190 (1938); Harkins, W. D., and Matton, R. W., *Phys. Rev.*, **53**, 911 (1938).

Let it be supposed that when any single X layer is deposited on the down trip of the slide it collects no charge, but that on the upward movement, when no film is deposited, the outer surface of the X layer takes up a positive charge. This would produce an induced charge in the surface of the metal on which the layer is de-

FIGURE 52. Film potentials of five different X multilayers on gold made from solutions 1(0, X), 2(Δ, □), and 3(●). The potential increment is about 100 mv/layer up to 20 layers.

posited. The general Gauss-Poisson equation for the potential is $\Delta^2 V = -4\pi meT/\epsilon$ for a condenser which consists of two equally charged parallel plates, in which n is the number of unit charges per sq cm, e is the electronic charge, T is the total thickness of the dielectric (X layers, paraffin, etc.), and ϵ is the dielectric constant of the dielectric under the plane of the charge. Thus if all the charge of a multilayer is associated with the *outer* layer only,

$$\Delta V = 4\pi neNt/\epsilon, \quad (1)$$

where t is the constant thickness of each X layer, and N is the total number of X layers. Thus the potential is proportional to the number of layers, as is nearly true (Figs. 52 and 53).

If, however, an equal charge is deposited on each X layer and persists, then the potential will rise much more rapidly than with the first power of the thickness, which

is contrary to a part of the experimental results presented later. The relation for equal charges retained on the surface of every layer is

$$\Delta V = 4\pi netN(N+1)/2\epsilon, \quad (2)$$

where ne is the surface density of the charge, t is the thickness of each X layer, and N is the total number of X layers. Thus if one X layer increases ΔV by 0.1 volt, then 20 X layers would give a potential of 21 volts. Experimentally, 20 X layers give

FIGURE 53. Film potential for each of 22 single layers of an X film on gold. Average slope 75 mv per layer.

a potential of about two volts. The relations are modified if X layers are deposited upon a dielectric which covers the metal. Two different distributions of charge are considered below.

(1) A definite charge, whose value is independent of the thickness of the initial dielectric and of the X multilayer, is present on the outside layer only. For simplicity the thickness (T) of the dielectric is represented by $T = Mt$, where t is the average thickness of the X layers in a multilayer. The dielectric constant of the dielectric is ϵ_D and that of the X multilayer ϵ . Then

$$\Delta V = 4\pi net(M/\epsilon_D + N/\epsilon). \quad (3)$$

(2) A charge of a certain constant value remains upon every layer of the X multilayer. Then

$$\Delta V = 4\pi net \left[\frac{NM}{\epsilon_D} + \frac{N(N+1)}{2\epsilon} \right]. \quad (4)$$

It is evident that if each X layer is to retain its charge and if the multilayer is deposited directly on the metal, the charge must decrease rapidly with the distance from the metal if the film potential is to be proportional to the number of X layers.

Thus to meet this condition the charge densities on successive layers must be $\rho/1$, $\rho/2$, $\rho/3$, . . . ρ/N .

The difference in the potential increments according to Eqs. (3) and (4) are illustrated by listing the potentials calculated for the case in which the thickness of the initial paraffin layer is equal to that of 100 X layers and the potential increment by Eq. (1) is 0.1 volt per layer. For simplicity the dielectric constants of the paraffin and the X multilayer are supposed to be the same. Actually that of the paraffin is somewhat lower (Fig. 54).

FIGURE 54. Film potential of an X multilayer on a moderately thin sheet of paraffin on gold. Average slope 900 mv per layer.

The way in which the charges are built up on X and Y multilayers is shown by work in this laboratory.⁷⁷

The method used seems to offer promise of revealing much that occurs in the production of a film potential when X or Y multilayers are built upon a metal at various values of pH of the subsolution utilized. This consists in measuring the electric current, or charge, which passes between the metal slide upon which the film is deposited, during its up and down trips, and another (comparison) electrode of the same metal (gold), immersed in the solution. In using this method there are several difficulties which must be kept in mind.

(1) If one electrode has been in the solution for a long time (*e.g.* $\frac{1}{2}$ hour), and the other is now dipped into the liquid, a relatively large current flows between them during the first few seconds, even after the slide has ceased its motion.

(2) If both electrodes have been (partly) immersed for a long time, a small current usually flows, probably because there are small differences in the metal surfaces or the adjacent solutions.

(3) A current passes between the electrodes while one of them is being dipped into the solution through a clean surface. During the down trip this flows in the opposite direction from that during the up trip. This current is due to the constant galvanic potential between the metal electrode and the solution, and the change in capacity during the dipping.

In the experiments current (2) is made zero by adjusting the depth of immersion of the comparison electrode. The disturbing current (1) disappears if both electrodes are immersed for a long period, or if several layers have been deposited on the slide, thus insulating it from the solution. The disturbing current (3) also decreases with the number of layers since the capacity between the electrode and the solution also decreases.

If it is desired to study the currents due to the first few layers, both electrodes should be dipped synchronously: one through the monolayer on the subsolution, and the other through a clean surface of the latter.

The first experiments consisted of dipping clean gold through the clean surface of a solution buffered at pH 9.4. Apart from currents (1), which become very small after the first few dips, there first appear, during both the up and down trips, currents of about the same magnitude but in opposite directions for the two. These currents show that the potential of the gold electrode is negative with respect to the solution. No currents flow if the slide emerges wet, as it may if the upward movement is very quick. This is because the electric double-layer of the gold and solution is removed with the wet slide, and is not disturbed as when the gold emerges dry.

During the deposition of X films at a pH of 9.4, there appear, apart from currents (1), quite the same currents as are produced by dipping clean gold through a clean surface of the solution, but the currents become smaller and change sign as the dippings increase. This reversal of sign takes place when the X film has attained a potential of about 0.4 volt. After this the currents have almost a constant value, or decrease slightly with the number of layers.

During the up trip the positive current flows from the comparison electrode through the solution to the X multilayer, and in the opposite direction on the down trip.

An X multilayer, with a positive charge on the outside layer may be dipped into the solution, when it is found that if the film potential before the dipping was greater than about 0.5 volt, say 2 volts, a positive current flows through the solution from the multilayer to the gold of the comparison electrode. If the system X multilayer-gold is now removed from the solution it exhibits a decrease of film potential, the magnitude of which increases with the time of immersion. Thus the current during the down trip with X deposition, has the same direction as the discharging current specified here.

The total charge transferred during the down or up trip is of the same order of magnitude, as closely as could be calculated from the preliminary data, as the charge on the outer surface of the multilayer would need to be to give the measured film potential.

From the above it is not necessary to conclude that the film is completely discharged during the down and charged again on the up trip. It is possible that a double layer is formed between the surface of the film and the solution. In any

event the potential with respect to the solution is reduced when the multilayer-metal system is in the solution.

If the slide is allowed to remain at rest at its deepest immersion, no current flows when the number of X layers is small, but with a larger number of layers a very small discharge current is observed. The increment of potential per layer of

FIGURE 55. Effect of pH on film potentials.

an X multilayer is known to decrease with the number of layers, so if the potential is due to a charge on the outermost layer only, this charge must also decrease at the same rate. It is possible that this is due to a partial discharge of the film during its building, through the action of the small currents just described.

In the production of Y films at pH 7.0 the relations are different. During the down trip the current always flows through the solution from the comparison electrode to the slide plus multilayer, and in the opposite direction during the up trip, until, usually, the film potential attains a value of about 0.2 volt. After this the potential does not increase, since now both currents fall to almost zero.

INTERMOLECULAR FORCES AT SURFACES AND INTERFACES

The term "monolayer" and what is known as the monomolecular theory have led to certain false points of view according to which the energy of the film is restricted to the single layer of molecules in the oil film itself. In Volume VI of this series, in the chapter on solids, it will be shown that the attraction of anatase (TiO_2) for water remains appreciable through all of the five first layers of water molecules, although the energy falls off almost exponentially with the distance.

The attractive energy between the molecules in the monolayer, and between these and the water are of many different types, of which the dispersion and dipole forces are the most important in the more usual types of insoluble films.

Whenever there is homogeneous binding in a solid or a liquid body the general energy equation may be written

$$E = -aV + bA,$$

in which a and b are constants, V is the volume of the body, and A is the area of the surface. At the surface there are so few bonds that the binding energy is less.

The types of bodies to be considered are:

(1) Liquids

- (a) Non-polar
- (b) Semi-polar
- (c) Polar
- (d) Metallic

(2) Solids

- (a) Ionic Crystals (as salts)
- (b) Metals
- (c) Semi-conductors
- (d) Valence Crystals (diamond, carborundum)
- (e) Molecular Crystals

The energy of molecular attraction for parts of molecules may be expressed in terms of the potential (V) as outlined in a simplified form:

$$(1) \text{ Ion-Ion: } V = \frac{e_1 e_2}{R}, \text{ a scalar}$$

$$F = \Delta V = \frac{e_1 e_2}{R^2}, \text{ a vector.}$$

$$(2) \text{ Ion-Dipole: } V = \frac{e\mu \cos \theta}{R^2}, \text{ where } \mu \text{ is the dipole moment.}$$

$$(3) \text{ Dipole-Dipole (Head-on) } = \frac{2\mu_1 \mu_2}{R^3}$$

General:

$$V = \frac{\mu_1 \mu_2}{R^3} (\cos \gamma - 3 \cos \theta_1 \cdot \cos \theta_2),$$

where γ is the angle between the vectors of the dipole moments.

$$(4) \text{ Atom-Ion: } V = \frac{aze^2}{2R_4}$$

(5) Dipole-Dipole Polarization or Dispersion Forces:

$$V \propto \frac{1}{R^6}$$

$$(6) \text{ Ion-Metal (Mirror Image): } V = \frac{e^2}{4a}$$

(7) Dipole-Metal (Mirror Image):

$$V = -\frac{\mu^2}{16a^3} - 2 \cos \theta_1 \cos \theta_2 + \sin \theta_1 \sin \theta_2 \cos (\theta_1 - \theta_2),$$

$$\text{or for a dipole directed toward the surface: } V = -\frac{\mu^2}{8a^3}.$$

R = distance, a = distance from surface, e = electronic charge, V = dipole moment, α = polarizability, z = valence, F = force, θ = angle.

Since the dipole-dipole interaction energy varies as the cube of the distance, the

effect is still appreciable, in the case of films of alcohols, acids, and others of this type, in the second layer of water molecules.

A more pronounced effect is the orientation effect of the dipoles of the film upon those of the water.

THE HYDROGEN BOND IN "MONOLAYERS"

The energy of molecular interaction in many "monolayers" which contain hydrogen in the polar group, and between the molecules of the "monolayer" and the aqueous subphase, is considerably increased by a special type of interaction between the hydrogen and two other atoms. This interaction is commonly designated by the term "hydrogen bond."

The effect of this bond upon the structure of the surface region is very great, since it gives a bond between molecules which is highly directional, and in this sense, though its energy is much lower, resembles to some extent a covalent bond. The depth of the surface region may be considered to be the thickness of all of that layer in which either the intermolecular energy or the structure is different from that in the interior of the subphase itself. The depth to which the energy is different is very small, but certainly more than one molecular layer of water is affected. Thus

FIGURE 56. Two molecules of water held together by a hydrogen bond. The dashes represent a region of negative charge. Free rotation may occur about the hydrogen bond.

The $\text{O} \begin{matrix} \text{H} \\ \text{H} \end{matrix}$ angle is 105° .

the surface region is several molecules in thickness, since it includes the monolayer of oil and several layers of water.

The hydrogen bond was first recognized by Moore and Winnill, and later by Pfeiffer, and the application of the idea was widely extended by Latimer and Rodebush and by Huggins.*

The hydrogen bond has a relatively small energy, which is in calories per mole: alcohol 6.2, ice 4.5, acetic acid 8.2, benzoic acid 4.3, etc. The strength of hydrogen bonds between atoms decreases in the order: fluorine, oxygen, nitrogen, chlorine. The strength of the bond should increase with increase in the electronegativity of the atoms, and with their size.

Water may be assumed to be very nearly tetrahedrally coordinated as in the model of Bernal-Fowler† (Fig. 56). Free rotation but no bending at the hydrogen bond

may be assumed, with an angle for $\text{O} \begin{matrix} \text{H} \\ \text{H} \end{matrix}$ of 105° .

* Moore, T. S. and Winnill, T. F., *J. Chem. Soc.*, **101**, 1635 (1912); Pfeiffer, P., *Ann.*, **398**, 137 (1913); Latimer, W. M. and Rodebush, W. H., *J. Am. Chem. Soc.*, **42**, 1419 (1920).

† Bernal, J. D., and Fowler, J. *Chem. Phys.*, **1**, 515 (1933).

In alcohol (ROH) the bond angle (Fig. 57) may also be taken as 105° . The extent of molecular orientation is dependent upon the location of the charge distribution in a polar molecule. Thus in nitro derivatives and nitriles the charge distribution is much more shielded than when $-\text{OH}$ groups are involved, and the effect is much smaller in comparison with the magnitude of the dipole moment.¹⁰⁰

FIGURE 57. Hydrogen bonds in alcohol.

If ice is melted only about 15 per cent of the hydrogen bonds are ruptured, but if it is sublimed all of these bonds are broken. Of the resultant heat of sublimation, $12.2 \text{ kcal mole}^{-1}$, only about one-fourth can be attributed to van der Waals forces, and about 9 kcal mole^{-1} to the rupture of hydrogen bonds. The higher hydrogen bond energy in alcohol ($6.2 \text{ kcal mole}^{-1}$) as compared with water (4.5) seems to be related to the smaller (2.70 \AA) $\text{O}-\text{H}-\text{O}$ distance in alcohols as compared with that in water (2.76 \AA).

In formic acid, a simple carboxylic acid, this distance is still less (2.67 \AA). In acetic acid the bond energy is $8.2 \text{ kcal mole}^{-1}$. In water the hydrogen bonds do not have a sufficiently high energy to give an appreciable concentration of polymeric molecules in the vapor phase, but the stronger hydrogen bonds of formic and acetic acids give stable double molecules which vaporize as such.

In Volume I, pages 222-6, of this series the writer showed that the value of h/λ for acetic acid (0.336) is much higher than for methyl (0.164) or ethyl (0.186) alcohol. Here h is the total energy absorbed when the molecule moves from the interior of the liquid into the surface, and λ that absorbed when the molecule moves from the interior of the liquid into the vapor. The values refer to a corresponding temperature of 0.7 . In the case of the alcohols all of the hydrogen bonds must be broken in the process of vaporization, while this is not true for acetic acid, which makes λ much higher relatively for the alcohols. Since when the molecules move into the surface no hydrogen bonds need to be broken, the value of h/λ should be much smaller for the alcohols, as the data indicate to be true.

In the $-\text{SH}$ group of the mercaptans the proton is buried more deeply in the electronic atmosphere of the sulfur atom than in that of the oxygen atom of $-\text{OH}$. Thus the hydrogen bonds in the monolayer of a mercaptan, and between the $-\text{SH}$ groups and the oxygen of the water have a considerably lower hydrogen bond energy than in the case of the otherwise similar alcohols. This is made evident by the difference in the magnitudes of the work of adhesion (W_A) at 20° C . Thus to pull an alcohol from the surface of water requires about 92 erg cm^{-2} of work, while for a mercaptan the value is only 75 per cent as large. With nitriles the very much

higher value of the dipole moment (3.6×10^{-18} instead of 1.7×10^{-18} for alcohols) keeps the work of adhesion toward water about as high as with the alcohols.

An interesting paper by Alexander,* gives somewhat definite pictures of the hydrogen bonding in the monolayer and between the monolayer and the water. He concludes that intra-monolayer bonding in alcohol films cannot occur, but his ideas postulate much less flexibility in the alcohol chains and more exactness in orientation than seems probable. It seems preferable to assume that condensed alcohol monolayers are held together by (1) van der Waals forces between the chains, (2) hydrogen bonding between the polar groups in the monolayer, and (3) hydrogen bonding between an alcohol and a water molecule. This may then be bonded to either a second alcohol or another water molecule. At low film pressures alcohols give the smallest molecular areas of any of the substances thus far investigated, although some other substances such as amines on a basic subphase, have given rather low areas but have not been investigated with sufficient exactness to determine just what these areas are.

ADSORPTION

The section on Liquids is not complete without a consideration of the extremely important subject of adsorption. However, the thermodynamic theory of adsorption in liquids is the same as that when solids are involved, so both types of systems should be treated together. For this reason, adsorption will be treated in Volume VI of this series, after the Surfaces of Solids have been discussed.

On account of the importance of adsorption isotherms, and of their use in the determination of area, a bare outline of a subject which will be treated fully in Volume VI, is given in the three following sections.

A Method for Determining the Absolute Area of a Very Finely Divided Solid

Several important advances, which may be utilized in the determination of the area of either a crystalline powder or a porous solid, have resulted from the work (unpublished) of Dr. George Jura and the writer. These are described very briefly in this and the two following sections.

If a finely divided powder is placed in the saturated vapor of a liquid, it becomes covered with a film adsorbed from the vapor. If the liquid exhibits a zero contact angle with the solid, the adsorbed film at equilibrium is duplex (see p. 15), that is, the surface energy of the outer surface of the film is exactly that of the pure liquid. For example, if the vapor is that of water, the surface energy of the outer surface of the film is $118.5 \text{ erg cm}^{-2}$ at 25°C . If the powder is now dropped into the pure liquid contained in an extremely sensitive calorimeter, heat is liberated, and the total amount of this heat Q , in ergs, is equal to the total area (Σ) of the powder multiplied by the surface energy of the liquid ($118.5 \text{ erg cm}^{-2}$ for water).

Thus

$$Q_{\text{ergs}} = 118.5 \Sigma$$

or

$$\Sigma = \frac{Q_{\text{ergs}}}{118.5} \text{cm}^2$$

If q is the heat liberated per gram of powder, then

$$\Sigma = \frac{q}{118.5} \text{cm}^2 \text{g}^{-1}$$

This method, applied to a sample of titanium dioxide (anatase) pigment, gave an area of 13.8 square meters per gram. The area of this powder, as calculated by the method of Emmett, Brunauer, and Teller, from an adsorption isotherm of nitrogen, is 13.9, or almost the same. The result of the calculation by their theory involves

* Alexander, A. E., *Trans. Faraday Society*, 37, 426 (1941).

the assumption that the mean area occupied by a nitrogen molecule is 16.2 \AA^2 , while our method involves no such assumption.

In our work, each small crystal becomes coated with about five molecular layers of water (or ten of nitrogen) and we have already measured the effect of distance upon the energy of attachment of the liquid to the solid. The energy of vaporization of water is $10,480 \text{ cal mole}^{-1}$, and for successive layers on anatase, the values are higher than this in the successive layers as follows: (1) 5400, (2) 500, (3) 110, (4) 60, (5) 20, and all beyond 5 about 30 cal mole^{-1} . Thus it is obvious that with the duplex film, no error is due to the effect of the solid.

In practice, a correction is made for the thickness of the water film, since this causes the area of the film coated crystals to be slightly greater (less than 1 per cent) than that of the solid. The thickness of the water film is given by the weight of water adsorbed, divided by the area.

An Adsorption Isotherm with a Wide Range of Validity

The equation which represents the pressure-area relation of a condensed monolayer, either liquid or solid, on water, is

$$\pi = b - a\sigma \quad (1)$$

Here π is the film pressure, σ is the molecular area in \AA^2 , and a and b are constants.

We have found that this *same equation* is valid for adsorbed films or solids. The *very remarkable* fact which emerges is that the equation is valid, not only for the condensed monolayer, but also when the film grows to 2, 3, 4, 5, and even more monolayers in thickness, *i.e.*, both for polymolecular films and condensed monolayers without a change of the values of the constants.

The application of this equation to a large number of solids involves a considerable amount of calculation, since the film pressure π must be found by an integration of the Gibbs adsorption equation.

On this account the equation was transformed into the following equivalent relation:

$$\log p = \frac{-A}{v^2} + \quad (2)$$

in which p is the pressure of the vapor which is in equilibrium with the surface of the solid, and v is the volume of gas, at standard pressure and temperature, which is adsorbed per gram of solid.

This is the simplest adsorption isotherm thus far discovered which is valid over any considerable range and it seems to be valid over a greater range of pressures than any other isotherm. Comparisons have been made for 65 solids, of areas from 2 to 600 square meters per gram.

The Langmuir isotherm is not valid for any of these solids. The isotherm of Brunauer, Emmett, and Teller,* gives an excellent fit over a considerable range, while our new isotherm exhibits agreement between its linear form and the data over a much greater range of pressures, and especially to very much higher pressures. Thus with nitrogen on barium sulfate the data fit the linear relation up to a pressure of 722 mm, or to 0.95 per cent saturation.

* Their equation is:

$$\frac{p}{V(p_0 - p)} = \frac{1}{V_m C} + \frac{(C - 1)p}{V_m C p_0}$$

which is much more complicated than our isotherm in Eq. (2).

A New Method for Determining the Area of a Porous or a Non-porous Solid Without the Assumption of a Molecular Area

Until 1938 there was no good method for the determination of the area of a crystalline powder and a porous solid. At that time, the method of Emmett, Brunauer, and Teller, described by Emmett elsewhere in this volume, became fully developed. Its principal disadvantage is that the application of their theory to an adsorption isotherm does not give an area, but only the number (N) of molecules in the first monolayer. In order to determine the area, it is necessary for them to use the relation:

$$\Sigma = N\sigma$$

in which σ is the mean area per molecule of the substance used, usually nitrogen. Emmett's value for σ , as calculated from the density of liquid nitrogen, is 16.2 \AA^2 , while from that of solid nitrogen he calculates 13.4. Since there is no basis for the choice of one of these values rather than the other, or of some other value of the same order of magnitude, a considerable uncertainty is introduced.

The New Method. Values are obtained at constant temperature for the amount of nitrogen (or water, etc.) adsorbed on one gram of solid at pressures (p) up to saturation.

The value of $\log p$ is plotted on the Y-axis, and that of $\frac{1}{v^2}$ on the X-axis. The square root of the slope of the straight line gives the relative area of the solid. The area (Σ) per gram of solid is given by

$$\Sigma = ks^{\frac{1}{2}} = kA^{\frac{1}{2}} \quad (3)$$

where k is a constant for nitrogen and s is the slope of the straight line determined from any single solid by the method just described.

The best value of k is, at present, 4.06, so that the area of any solid is given by:

$$\Sigma = 4.06 s^{\frac{1}{2}} = 4.06 \frac{\Delta \log p}{\Delta \left(\frac{1}{v^2} \right)} \quad (4)$$

This simple equation has been used to calculate the area of 85 solids of areas of from 2 to 600 square meters per gram, and has in every case given an area within 10 per cent of that which may be obtained from the equations of Brunauer, Emmett, and Teller, by the assumption that nitrogen has the same area on all surfaces of solids.

However, a comparison of the two methods shows that the assumption that the area of the nitrogen molecule is constant is certainly invalid.

Solutions of Soaps and Detergents as Colloidal Electrolytes

JAMES W. MCBAIN

Department of Chemistry, Stanford University

It was found by McBain and his collaborators¹ that, in very dilute solution, a pure salt of a higher fatty acid—a soap—behaves as an ordinary electrolyte, but that as the concentration is increased it exhibits typical colloidal properties. McBain therefore defined colloidal electrolytes as electrolytes in which one ion is partially or wholly replaced by conducting colloidal particles, spontaneously formed in the solution. The soaps were the first and most thoroughly studied of this great class of colloidal electrolytes, but it was recognized from the outset that there must be innumerable other examples, including dyes, detergents, and biocolloids—indeed all ionizable organic compounds of not too low molecular weight. There are also several inorganic representatives, such as sodium silicates. Krafft² in 1896 pointed out that cetyl amine hydrochloride resembled soaps in its properties.

Hence we recognize anion-active and cation-active colloidal electrolytes, and a few cases in which, like Reyckler's³ triethyl cetyl ammonium cetyl sulfate, or the more recent commercial lauryl pyridinium laurate or lauryl pyridinium lauryl sulfate, both anion and cation are active. The great majority of the modern synthetic

detergents are anion-active sodium salts, though some are cation-active. There are a few, moreover, which are not electrolytes at all, such as nonyl glucoside, or such commercial non-electrolytic detergents as the Peregals, Emulfors, and Igepals, which are long-chain compounds of high molecular weight, exhibiting close similarity to the surface properties of the colloidal electrolytes.

Historical

Thirty years ago it was assumed that colloids had no very definite properties, and that they were exceedingly subject to change, depending upon their history. It was supposed that a colloid could not conduct; nor could it have a definite quantitative, easily measurable effect on lowering of freezing point or vapor pressure. Such of these properties as were observed were ascribed to impurities or products of hydrolysis or decomposition.

However, the most important result of the study of pure soaps was to establish that their solutions have definite, reproducible properties, easily rendered independent of their history, like those of sugar or potassium chloride. This laid the sound, permanent foundation for the study of this subject.

The main result, then, was to show that certain colloidal particles form spontaneously from ions, molecules or crystals; that they enter into true reversible equilibrium with these; and that therefore colloidal electrolytes are truly stable in the strictest thermodynamic sense.

So novel was this finding that when in 1925 some of the evidence for it was presented to the Colloid Committee for the Advancement of Science in London, it was dismissed by the Chairman, a leading international authority, with the words, "Nonsense, McBain."

These stable colloidal particles have a self-organizing structure based on the principle of like to like. Polar groups are exposed to water, and hydrocarbon groups to hydrocarbon groups, to minimize interfacial energy and leave, instead, the maximum number of water molecules in mutual contact. Thus each molecule has its soluble groups outside, and its insoluble portions exposed as little as possible. Several structures have been suggested in which this purpose may be accomplished.

Soap Solutions

The proof that soaps are colloidal electrolytes and that such a class had to be recognized lies in the quantitative comparison of different kinds of physical chemical data, since any one kind, standing alone, might be explained by some other hypothesis.

First it had to be shown that hydrolysis is almost negligible, except in very dilute solution, so that the properties are those of the soap itself. Hydrolysis alkalinity never exceeds $N/1000$, and where desired it is readily suppressed by adding a slight excess of free hydroxide, which does not combine with soap.⁴

Then it was found that soap solutions conduct excellently; in fact, in concentrated solution their equivalent conductivity is almost as great as that of an organic salt such as sodium acetate. On the other hand, their osmotic effects, such as lowering of freezing point, of vapor pressure, of dew point or of osmotic pressure itself, are only moderate, being less than half what one would expect for an ordinary salt.

This contrast between electrical and osmotic behavior could be explained only by making two assumptions; first, that when these two physical chemical properties departed from the normal behavior of an ordinary salt, and also from each other, a colloid must have formed in the solution; secondly, that the colloid must exhibit quite appreciable conductance. There is universal agreement on these points.

This conclusion follows from a quantitative consideration of two different kinds of physical chemical measurements, which could not have been arrived at with certainty through either alone; and it illustrates the great importance of using all available methods of study. Upwards of two dozen have so far been applied.

Typical osmotic behavior is illustrated by Figure 1 (due to S. A. Johnston and A. P. Brady) for solutions of potassium oleate. The osmotic coefficient g is defined as the ratio of the observed lowering of freezing point to that which would be expected for an ideal fully dissociated electrolyte forming two ions:

$$g = i/2 = 1 - j = \frac{\theta}{2 \times 1.858 m}$$

where g is the osmotic coefficient, i is van't Hoff's coefficient, j is the function of Lewis and Randall, m is the molality, 1.858 is the molal lowering for any ideal solute, and θ is the observed lowering of freezing point in degrees.

For comparison, the behavior of a real electrolyte, potassium chloride, is also shown in Figure 1.

FIGURE 1. Comparison of the Osmotic Behavior of Potassium Oleate as Colloidal Electrolyte with that of Potassium chloride as Typical Strong Electrolyte. The osmotic coefficient, g , is the lowering of freezing point observed divided by 3.716 times the molality, m .

It is seen that the behavior of potassium oleate and potassium chloride is similar in extreme dilution; but that over the range $0.0004m$ to $0.06m$, a 150-fold change in concentration, the value of g falls away to one-tenth of that for potassium chloride of the same concentration. The activity coefficient, of course, falls to a much lower value and continues to fall, whereas the g value somewhat abruptly begins to rise again in higher concentration.

Figure 2 (due to O. E. Bolduan) shows the osmotic behavior of the potassium salts of the saturated fatty acids of twelve, ten and four carbon atoms. The distinctive behavior of the soaps is entirely lost in potassium butyrate, where hydration effects obscure all others in high concentration.

Figure 3 (taken from McBain, Laing and Titley⁵) reproduces a series of conductivity curves of soaps at 90° and at room temperature, showing the family relations between the fall in conductivity in rather dilute solution, followed by a

minimum between 0.05 and 0.1*N* solutions, followed by a large increase in conductivity in higher concentration.

It is generally agreed that the only possible explanation of the great decrease in osmotic behavior and conductivity is that ions are replaced by colloidal particles, which, although conducting, have a lower equivalent conductivity than the ions from which they are formed. There is disagreement only as to the kinds and shapes

FIGURE 2. Comparison of the Osmotic Behavior of Potassium Salts of the Saturated Fatty Acids, with twelve, ten and four carbon atoms.

of colloidal particles involved. The experimental data have been substantiated by ultrafiltration⁶ and by measurements of electromotive force using hydrogen⁴ and sodium and potassium amalgam⁷ electrodes.

The main conclusions as to the constitution of colloidal electrolytes as outlined above remain unaffected by the fact that, at the time they were deduced, strong electrolytes were considered to be incompletely ionized until after the adoption of the Debye-Hückel theory (1923).

Solutions of Dodecyl Sulfonic Acid

Lottermoser and Püschel⁸ were the first to publish data on nonhydrolyzable colloidal electrolytes. Their extensive conductivity measurements include the alkyl sulfates of sodium, potassium, hydrogen, silver, magnesium, calcium, barium, zinc, copper and iron, including the straight-chain alkyl groups containing between twelve and eighteen carbon atoms, supplemented by measurements of electromotive force as well as of surface tension. They found that in very dilute solution the behavior

FIGURE 3. Equivalent Conductivity of Soap Solutions at 18° and at 90°.

is like that of a strong electrolyte; then at the following critical concentrations for univalent salts the conductivity and activity suddenly fall to low values by formation of colloid:

| | |
|----------|------------------------|
| C_{12} | 0.003–0.006 <i>m</i> |
| C_{14} | 0.0016–0.0025 <i>m</i> |
| C_{10} | 0.0004–0.0006 <i>m</i> |
| C_{18} | 0.0003 <i>m</i> |

Thereupon there is a minimum in the curve of equivalent conductivity at 60° observed for:

| | |
|----------|---------------------|
| C_{12} | 0.1–0.2 <i>m</i> |
| C_{14} | 0.1 <i>m</i> |
| C_{10} | 0.05 <i>m</i> |
| C_{18} | 0.025–0.05 <i>m</i> |

Finally, there is a maximum in the conductivity at 60° for:

| | |
|----------|---------------|
| C_{12} | 0.75 <i>m</i> |
| C_{14} | 0.5 <i>m</i> |
| C_{10} | 0.25 <i>m</i> |
| C_{18} | 0.25 <i>m</i> |

Similar conductivity measurements were later supplied by Hartley,⁹ Howell and Robinson,¹⁰ Ward,¹¹ Tartar and collaborators,¹² and several others. McBain and Betz¹³ were the first to study the straight-chain sulfonic acids, measuring conductivity, lowering of freezing point, and electromotive force.

By far the most carefully studied colloidal electrolyte is lauryl sulfonic acid, a highly soluble, non-hydrolyzable, free acid, based upon a paraffin chain of twelve carbon atoms.

FIGURE 4. Quantitative Data for Solutions of the Typical Colloidal Electrolyte; Lauryl Sulfonic Acid; including Conductivity, μ , Transport Number, T.N., Osmotic Coefficient, g , Integral Diffusion Coefficient, 1D, Differential Diffusion Coefficient DD, Dye Solubilization, Dye, Surface Tension, σ , to show the shape of each curve and the actual concentrations at which maxima and minima occur for different properties.

Figure 4 shows data for lauryl sulfonic acid, all from the Stanford University laboratory, comprising conductivity,^{13, 14} transport number,¹⁵ lowering of freezing point,^{13, 14} diffusion,¹⁶ dye solubility,¹⁷ and surface tension.¹⁸ (The other surface properties are presented in Figure 12, since surface anomalies occur only in the lowest range of concentration, before the fall in conductivity and freezing point begins).

The equivalent conductivity of lauryl sulfonic acid at 25° falls rapidly at between 0.008 and 0.009*m* to a minimum, where it is 39 per cent of its value for infinite dilution; then it rises again steadily.

The osmotic coefficient falls off at 0.00105*m* at 0° and becomes nearly constant at 0.085*m*, at a value between 14.5 and 16 per cent of that for infinite dilution, as compared with the 39 per cent for conductivity.

The transport number of the alkyl group or sulfonic radical is but little affected from its value for complete dissociation at infinite dilution, 0.059 equivalent per Faraday of current, until 0.016*m* (where g and conductivity have both fallen to

65 per cent). Then the transport number rises to a sharp maximum at $0.055m$ with a value of 0.35 equivalent per Faraday of current. Thus its rise lags far behind the formation of colloid as shown by conductivity and freezing point, but its maximum is reached well before the minimum in conductivity is reached. Thereafter it falls again, rapidly at first, to a value of 0.22.

The diffusion coefficient likewise passes through a sharp minimum. For the integral diffusion coefficient this is at $0.07m$, but the true or differential diffusion coefficient shows the true minimum to be at $0.05m$, the same as the sharp maximum

FIGURE 5. The osmotic coefficient of the Wetting Agent and Detergent "Tergitol 4," sodium tetradecylsulfate.

for transport number. Both diffusion coefficients then rise greatly to a value about 73 per cent that for infinite dilution, whereas the minimum for integral diffusion was 36 per cent and for differential diffusion coefficient 5 per cent of that for infinite dilution.

The dye solubility, to be discussed later, anticipates the fall in conductivity and osmotic coefficient, but otherwise is almost a mirror image of the g value, not changing after $0.1m$.

The surface tension has a sharp minimum at $0.005m$, 36 per cent of the value of water, then remaining constant above $0.01m$ at 47 per cent.

Attention should be drawn to the rather abrupt change in osmotic coefficient from a rapidly falling value to constancy, to the minimum in conductivity rising markedly with further increase in concentration, to the very deep and sharp mini-

mum in diffusion coefficient followed by a high value for all concentrated solution, and finally to the definite discrepancies between the concentrations at which these various effects are observed.

The writer finds it impossible to explain all these quantitative data without as-

FIGURE 6. The osmotic Coefficients of a series of the Wet-ting Agents and Detergents, Aerosol OT (dioctyl, 2 ethylhexanol), Aerosol MA (dihexylmethylamyl) De-tergents, Aerosol IB (diisobutyl), and Aerosol AY (diamyl), all esters of sodium sulfosuccinate.

suming the presence of many sizes and kinds of colloidal particles, shifting accord-
ing to the concentration.

Osmotic Coefficients of Colloidal Electrolytes

Tergitol 4, the sodium salt of the highly branched secondary tetradecyl sulfate, 7-ethyl, 2-methyl, 4-decanol sodium sulfate, is a typical colloidal electrolyte as shown by Bolduan's freezing point data in Figure 5.

Likewise the Aerosols, esters of mono-sodium sulfonate of succinic acid, are all colloidal electrolytes, the colloid forming at higher and higher concentrations as the alkyl groups of the ester decrease in size. It has been computed that this trade name could include over a million such compounds of which only a few dozen have been prepared. Bolduan's data for the Aerosols are given in Figure 6.

Two bile salts have also been measured by Johnston and Bolduan and are shown in Figure 7. Their formulas are

Sodium Desoxycholate

Sodium Dehydrocholate

FIGURE 7. The Osmotic Coefficient of the Bile Salts; the detergent sodium desoxycholate, and the non-detergent sodium dehydrocholate.

They are remarkable in that this minor difference in formula has such a profound effect on their properties. Sodium desoxycholate, like the other colloidal electrolytes, solubilizes otherwise insoluble dyes and hydrocarbons. Practically speaking, sodium dehydrocholate is not a colloidal electrolyte; it dissolves no dye, and it salts out hydrocarbons from water.

A. P. Brady at Stanford University has discovered that all existing freezing-point data for colloidal electrolytes may be placed upon one of three curves on the

same diagram, provided that the concentrations are brought to comparable values by multiplying with a constant for each substance. There is one normal curve on Figure 8 for all the straight-chain compounds, such as the saturated soaps, potas-

FIGURE 8. A. P. Brady's curves upon which all the osmotic coefficients of colloidal electrolytes may be placed by merely multiplying the concentration by an arbitrary constant in each case. The three curves are for straight-chain, branched and cyclic compounds, respectively; the dotted curve is the physical limit for any solution remaining homogeneous instead of separating into two layers; the lowering of freezing point and activity would then remain constant over this range.

sium octoate, decylate, and laurate, lauryl sulfonic acid, sodium decyl sulfonate, sodium dodecyl sulfonate and the cation-active dodecyl amine acetate.¹⁹ There is another curve for the branched-chain compounds: Aerosols, Tergitol, potassium oleate, and $C_{11}H_{23}COOC_2H_4NHCOCH_2N(C_2H_5)_3Cl$. The third curve is for the polycyclic bile salt. All the existing data fall on the curves within the experimental error. A fourth dotted line has been drawn in to show how steeply the osmotic coefficient would fall in the extreme limit, where the activity and lowering of freezing point remained actually constant, and the solution would fall apart into two layers of constant composition. It is seen that all the curves have less slope than this, and that the straight-chain compounds come nearest to it.

Other Examples of Colloidal Electrolytes

The danger of using only one physical chemical method is illustrated²⁰ by Figure 9, for the conductivities of methylene blue, meta benzopurpurin, and cetyl pyridinium chloride. The curve for cetyl pyridinium chloride resembles that of the soaps. That for methylene blue rises strikingly in very dilute solution, whereas that for meta benzopurpurin resembles an ordinary salt.

Hartley, Collie and Samis²¹ comment: "This is well illustrated by the equivalent conductivity-concentration curves for the two dyes, methylene blue and 'meta' benzopurpurin, and for the paraffin-chain salt, cetyl pyridinium chloride. The first has an equivalent conductivity rising *above its infinite dilution value* in very dilute solution, a phenomenon which seems to admit no other interpretation than the formation of (probably small) micelles. The second, which transport number measurements have conclusively shown to contain micelles, has an *apparently* normal conductivity.

FIGURE 9. The Conductivity of 3 Colloidal Electrolytes, Methylene Blue, Benzopurpurin and Cetyl Pyridinium Chloride, showing Three Types of Behavior all caused by Colloidal Particles.

The third shows, at a concentration of about $N/1000$, a very sudden *fall* of equivalent conductivity which, there is nevertheless very strong evidence to show, is accompanied by the formation of large micelles."

The conductivity of the bile salt sodium desoxycholate²² falls to the extent of only two-thirds, which is not a very pronounced departure from that of a salt, and the osmotic coefficient is lowered to one-third. This points to smaller, better-conducting micelles in the bile salt solution, presumably on account of the greater difficulty of close packing them in the colloidal particle.

The equivalent conductivities of some cation-active detergents²³ are shown in Figure 10. They resemble a homologous series of anion-active colloidal electrolytes.

Figure 11 includes data²¹ for the conductivity and the transport number (of the cation) of two cation-active detergents, cetyl pyridinium bromide and cetyl trimethylammonium bromide. It is noteworthy that, in these instances, the fall in conductivity is accompanied by a large increase in transport number, rising to a maximum of over 1.6 equivalents of cetyl radical per Faraday of current in 0.014*m* solution. Thereafter, the transport number decreases considerably while the conductivity continues to fall gently. The significance¹⁵ of such high transport numbers in excess of unity, like those obtained for sodium oleate,²⁴ is not that such an ion has a high conductance, but rather the opposite. This general misconception was contributed to by a well known diagram²¹ in which the conductivities shown here in Figure 11 were multiplied by the transport numbers and the results entitled the

FIGURE 10. Equivalent Conductivity, λ , and Transport Number, T_+ of Cetyl Pyridinium Bromide and of Cetyl Trimethylammonium Bromide at 35°.

FIGURE 11. Conductivities of Cation-active Detergents, the hydrochlorides of octyl-, decyl-, tetradecyl- and hexadecylamines.

"equivalent conductivities of the component radicals." This needs a note of explanation.

Always, in any electrolytically conducting solution, the total current is distributed among the carriers present, that is, all ions and colloidal particles. Hence each kind carries a fraction of the total current, and that fraction is the true or electrical transport number of that particular species of ion or particle. Hence true or electrical transport numbers are always less than unity. The conductivity of the part is always less than that of the whole. The transport of material, on the other hand, is equal to the true transport number multiplied by the number of equivalents of material associated with each electrical charge. If the same kind of material, such as bromine, is contained in more than one carrier, then the observed transport of that substance is the algebraic sum of the material transport numbers of all the kinds of carriers containing it.

Here, some bromine must be carried toward the cathode in the positively charged colloidal micelles or particles, out-weighing the bromine being carried toward the anode by the faster simple bromide ion. Hence the true significance of the data is not that the conductivity of the bromine is negative, as alleged, but that bromine constitutes a part of the positively charged colloid; and furthermore, to produce such a large gross transport number as 0.6 equivalent of total bromine toward the cathode per Faraday of current, there must be several atoms of bromine in the positive colloid for each free positive charge thereon. M. E. Laing²⁴ has shown how to combine conductivity and transport data so as to derive the actual composition of the average colloidal particle.²⁵

The conductivity and the osmotic pressure fall on account of the withdrawal of ions into the colloidal particle. The conductivity is most affected by the withdrawal of ions of opposite sign into the same colloidal particle.

Kinds of Colloidal Particles in the Solution

McBain originally tried to predicate only one kind of colloidal particle, but was forced to abandon this position entirely when it was necessary to take into account such independent quantitative physicochemical data as have been referred to above. He then adopted a spherical ionic micelle together with the much more poorly conducting lamellar micelle. There is direct proof of the existence of lamellar micelles by x-ray diffraction,²⁶ although this is not exhibited over the whole range of concentration in which colloid is present. The molecules are arranged parallel, side by side, in two layers showing side spacing, and the long spacing equal to double the length of the molecule. This evidence is ignored without reference by the English writers.

McBain's spherical ionic micelle was postulated as being comprised of not more than ten like ions retaining their charges. Such a particle would exhibit a corresponding lowering of osmotic coefficient, but must have an enhanced equivalent conductivity to the extent of $n^{2/3}$, where n is the number of like ions merged into one spherical particle. The principle is that of Stokes' Law, or like the rapid fall of a large raindrop compared to a similar weight of small drops of mist. The total force in this case, charge multiplied by applied electrical field, was the same before and after aggregation, but the resistance to movement is $n^{2/3}$ smaller for the one large sphere than for n small spheres. McBain²⁷ points out that the concentrations of ions must increase, however slightly, over the whole range of concentration, and that therefore the formation of ionic micelles must gradually increase from great dilution to high concentration. Small micelles, as in Figure 9 for methylene blue, would serve the same purpose, if the like ions were not over-burdened with too many opposite ions.

A complex of three ions, including two of like charge, will lower their contribution to the osmotic coefficient, g , to a third of the value for three free ions; but it

will also reduce the conductivity, since the one charge is now loaded. A complex of five ions, including two of like charge, will contribute greatly to lowering of g , but may enhance the conductivity. Thus a small micelle of whatsoever shape, if it has several charges, may resemble McBain's ionic micelle in its effect upon osmotic activity and conductivity and even upon transport number. Likewise, Hartley's suggested micelle of 50 ions of one sign and 30 of the other enhances conductivity instead of diminishing it, while lowering the contribution to g about five fold. Van Rysselberghe²⁸ calculates the composition of the average micelle which is required to agree with both conductivity and freezing point of lauryl sulfonic acid solutions. Taking both kinds of data together necessitates that the average composition of the micelle vary over the whole range of concentration, and that the first average product of aggregation be an ion pair.

The lamellar micelles, with their compensating ions, were shown by McBain^{24, 29} to conduct, in the case of sodium soaps, about one-fourteenth as well as an equal concentration of sodium chloride.

The majority of investigators, such as Adam, Stauff,³⁰ Hess,²⁸ Bury,³¹ Lawrence,³² and Meyer and van der Wyk³³ are of the opinion that several kinds of colloidal particles are to be found in the solution of a colloidal electrolyte, as was seen by Hartley to be necessary for methylene blue, Figure 9, p. 112.

In an important contribution, Meyer and van der Wyk³³ discuss the formation of large micelles by the successive addition of ions and ion pairs, pointing out that after the first few these involve approximately equal energy. Hence there would be a range of statistical distribution of sizes in each concentration. McBain³⁴ pointed out that, for the lower soaps, the first and simplest aggregate is just an ion pair and is there the first to occur. Bury *et al.*³⁵ showed that, for a large micelle, the application of the Mass Law would predict a fairly abrupt, although never a perfectly sharp, initiation of the formation of an appreciable quantity of micelles. This they call the critical concentration for micelles. We have seen that the micelles continue to be formed over a very wide range, at least until the minimum conductivity is reached.

Tartar¹² and Ward¹¹ adhere to an earlier suggestion of Hartley's that there is only one kind of micelle—spherical and of constant size—whose radius is determined by the length of the hydrocarbon group.

Aggregation of pre-existing micelles has likewise been proved to occur.³⁶ This may even lead to gelatinization of the type of a brush heap structure. Association is the key principle of colloids.

Most colloidal electrolytes whose conductivity has been carefully examined exhibit less falling off of conductivity in extreme dilution than is demanded by the Debye-Hückel theory of ions. (Compare the striking departure from methylene blue in Hartley's Figure 9.) For myristal sulfonic acid the conductivity in the initial range of concentration remains constant, as has been shown by unpublished work by M. E. L. McBain. McBain believes that, although in extreme dilution the colloidal electrolyte is practically all dissociated into free ions, nevertheless some ionic micelle must begin to form. Small micelles would behave similarly.

There remains for discussion only the rise in conductivity in concentrations above the minimum. Here, as was earlier done, instead of abandoning the Mass Law, which was relied upon for the critical concentration, Hartley³⁷ and Ward¹¹ attempt to explain it in terms of overlapping ionic atmospheres and changes in dielectric constant of water to comparatively great distances from the micelles. They consider that all the charges upon the surface of a particle are equivalent to the same charges concentrated in a point in the center of the particle or mass. However, the free electric charges on all micelles hitherto proposed are so far apart that McBain regards them as being practically independent, each having its own ionic atmosphere. It has been many times observed that the ionic strength is that of a uni-univalent electrolyte, since additions of indifferent electrolyte affect conductivity, freezing

point, etc., to about the same extent as if they were measured in the presence of uni-univalent electrolytes.⁸⁸

Surface Properties of Colloidal Electrolytes

Solutions of colloidal electrolytes exhibit remarkable surface properties. They greatly lower the surface tension of water and even lower the surface tension of hydrocarbons^{39, 40} in which they are soluble. A very dilute soap solution, for example, may have a surface tension as low as 25 dynes as compared with 72 dynes for water. This is far lower than 40 dynes for a close-packed film of oleic acid on water or 32.5 dynes for pure oleic acid itself. This fact constitutes one of the many proofs that surface tension is not completely determined by the exposed atoms or molecules, but that the surface is hundreds or even thousands of Ångströms deep. In many cases the surface tension in very dilute solution passes through a minimum, as was seen in Figure 4, followed almost immediately by a shallow maximum. Non-electrolytic detergents exhibit no minimum, but instead, after the first great fall in surface tension, remain at a constant value throughout all subsequent concentrations. Curves such as these for detergents have been classified as Type III curves, and well over 100 examples have been cited.^{41, 42} Similar curves are found for interfacial tension between oil and water.⁴³

All the surface anomalies occur in the neighborhood of this minimum, even although it lies below the so-called critical concentration for the formation of micelles.

For all concentrations after the surface tension has recovered from its minimum value, the surface is almost completely reversible and the surface tension independent of time. For all lower concentrations, the surface tension requires extremely long periods of time to come to a constant or equilibrium value.^{18, 44} In contrast, the actual adsorption in the surface is almost immediate, and independent of time.

The greatest anomaly, to which many authors have given anxious thought without finding a valid explanation, is the glaring contradiction between the adsorption and the surface tension data. The Gibbs theorem, according to which the adsorption, Γ , is proportional to the slope of surface tension, σ

$$\Gamma = -\frac{d\sigma}{d\mu} = -\frac{d\sigma}{dF} = -\frac{a}{RT} \cdot \frac{d\sigma}{da} = \text{approx} -\frac{c}{RT} \cdot \frac{d\sigma}{dc}$$

predicts positive adsorption for the first downward slope of surface tension; no adsorption whatsoever for the minimum where the surface tension of water is most lowered and both surface and solution are supposed to be 99.9 per cent water; negative adsorption just after the minimum, followed again by no adsorption at all! This is compared with the actual measurements by microtome and interferometer given below.¹⁸

| m | Interferometer | Microtome | Gibbs |
|-------------------------|----------------|-----------|---------|
| 0.0020 | +3.0 | +2.7 | +2.4 |
| 0.0060 (σ min.) | | +5.4 | 0 |
| 0.0062 | +3.1 | | 0 |
| 0.0084 | +5.3 | +3.7 | -8.7 |
| 0.0087 | | +3.9 | -11.2 * |
| 0.0113 | | +5.2 | -0.3 |
| 0.0117 | +1.8 | +5.2 | -0.2 |
| 0.0122 | | +5.7 | -0.2 |

* Here the Gibbs theorem predicts that there can be no lauryl sulfonic acid at all in a surface layer 12700 Å. deep, or correspondingly deeper if this is not pure water.

To save the situation, which is unparalleled elsewhere in science, many workers have made suggestions to save the Gibbs theorem, but unfortunately at the expense of the main principles of thermodynamics. The derivation of the theorem has been repeated by many writers and found to be rigorous back to the point where Gibbs

made his choice of terms or energies to be included in the first law of thermodynamics as applied to the case he had in mind. The latest suggestion, again thermodynamically unsound, is to use, instead of the activity of the colloidal electrolyte, the activity only of its simple ions.⁴⁵ However, it was overlooked, as is clear from Figure 4, that for laurylsulfonic acid, the phenomena occur below the critical concentration for micelles, and the calculated result would remain the same.

FIGURE 12. Surface properties of very dilute solutions of laurylsulfonic acid, such as surface tension, σ , showing that the marked anomalies occur below the "critical concentration for micelles" as deduced from conductivity μ and coefficient g . The curve with broad maximum is the maximum effect upon surface tension produced by suddenly enlarging the surface by sweeping. The sharp maximum represents the time required to recover from such sweeping, amounting to 3000 minutes.

Solutions of potassium chloride, bromide and iodide resemble each other in surface tension. Nevertheless,⁴⁶ in 0.0002*m* solutions the chlorides, bromides and iodides of cetyl pyridinium and of cetyl tri-methyl ammonium are 62, 52 and 37; 63, 52 and 44 dynes respectively.

The other anomaly^{47, 48} is that in these very dilute solutions which contain largely or only simple ions, not only is the time required to establish surface tension many orders of magnitude greater than that calculated from diffusion, but if the surface is compressed, a pellicle is formed upon it. The pellicle is a semi-denatured film which requires a definite pressure to be exceeded before the film will re-dissolve, whereas for small compression there is no pellicle and no anomaly in more concentrated solution where colloid predominates.

Figure 12 reproduces on a larger scale than Figure 4 the more dilute region of solutions of laurylsulfonic acid. The curves for conductivity μ and osmotic coefficient g , are given for comparison with the curve for surface tension, σ , to show that the minimum in surface tension at 1.55 grams per liter is well below the "critical concentration for micelles."

Only two other curves are drawn in Figure 12. Both exhibit a high maximum at or near the minimum for surface tension. Both refer to the effect on the float of a Pockels-Langmuir-Adam film balance filled with clean solution of laurylsulfonic acid. When the surface is enlarged by sweeping a barrier *away* from the float, a pull on the float is observed, a temporary increase in surface tension of the swept solution. The maximum effect, 23.5 dynes per cm, is produced at 1 g per liter, but the time required for this pull to disappear again is sharply maximum at 1.58 g per liter, being several thousand minutes; it has fallen to less than thirty minutes at the "critical concentration for micelles."

To avoid complicating Figure 12, some other results may be briefly summarized in words. In all solutions more dilute than the critical concentration, even a slight compression of the surface of laurylsulfonic acid solution, by moving a sweep a short distance toward the float, causes an initial pressure or push upon the float (a temporary reduction in surface tension) by crowding the molecules or ions that were in the surface. The effect steadily increases with dilution, and far greater initial pressures are produced below the critical concentration than above it. A permanent pressure is produced near and above the "critical concentration for micelles" which has a characteristic final value of about 0.5 dyne when nearly all the surface is compressed together.

Some Factors of Detergency

Since the discussions of this subject have recently been summarized,⁴³ it is sufficient to recall that the equation for detergent action is:

$$\text{fabric} \times \text{dirt} + \text{soap} = \text{fabric} \times \text{"soap"} + \text{dirt} \times \text{"soap."}$$

The action is a replacement of the unknown or undesired dirt by soap or a detergent, leaving the dirt suspended and protected by soap. The quotation marks indicate that very frequently acid or basic constituents of the soap predominate in the sorption compound.

Ordinary soap is the most universal detergent, whereas the soapless detergents are advantageous for specific purposes; such as washing wool and not cotton, etc.

The prerequisite for washing or detergency is wetting, as is easily seen when trying to wash a greasy dish. Hence we may select four factors;

1. Wetting: Due to surface tension and interfacial tension relations and to orientation of the ions or molecules in the surface.
2. Protective Action: Due to adsorbed film of detergent both upon the skin or fabric and upon the dirt removed.
3. Suspending Action: Due to the n free compensating ions of opposite charge which surround any charged particle, such as the remote dirt, and so in effect reduce its particle weight in the proportion $1/(1+n)$. This is only true for ionizing media and a further principle, such as orientation of solvent molecules, or cybotaxis, has to be sought in non-ionizing media.
4. Solubilization: Due to colloidal particles sorbing or including otherwise insoluble matter.

The solubilization of otherwise insoluble dye is an excellent test for colloidal particles. In critical experiments care has to be taken to avoid the mere suspending and protecting of pre-existing colloidal particles of dye by utilizing only large clean crystals of dye. The dye number for laurylsulfonic acid was given in Figure 4, and it was pointed out that it showed some colloid below the "critical" concentration for colloid. Addition of electrolytes favors the formation of colloid, and hence increases the dye number unless the colloid is completely formed already, after which further electrolyte depresses the dye number. Thus by suitable small addition of electrolyte, colloid can be produced in the most dilute solutions.

Numerical data for dye numbers have recently been summarized.⁴⁹

The dye number may be used to settle the question as to whether the dye dissolves

in the hydrophobic part of the micelle, as was suggested by Hartley for his spherical micelle; or alternatively that the dye is sorbed in and upon the micelle or included in layers in the lamellar micelle, as indicated by the x-ray studies of Hess and his collaborators.²⁷ If the dye is merely dissolved in the hydrocarbon part of the micelle, the amount so dissolved will be proportional to the amount of that hydrocarbon. In a homologous series, then, the dye solubility, in concentrations sufficiently high for the complete formation of colloid, should increase in proportion to the number of CH_2 groups in the paraffin chains.

This has been tested at Stanford University by Johnson. He found, for example, that the number of milligrams of dye solubilized per mole of the potassium salts of the saturated fatty acids were for potassium octoate 80, for potassium decylate 240, for potassium dodecylate 400, and for potassium tetradecylate 1400. This apparently disproves the suggestion of solution in the hydrocarbon portion of the micelle and lends weight to the x-ray evidence for the layers in the lamellar micelles.

Applications

Soap is used for cleansing, for making and breaking emulsions and foams, and for a number of specific purposes. Dyes need only mention.

Soapless detergents are used in a multitude of ways in aqueous and non-aqueous systems, apart from the detergent principles summarized above. For example, cation-active detergents are among the best germicides and fungicides, the effectiveness of all detergents depending upon pH. They are used in insecticides, and for drowning mosquito larvae. Detergents are used to make paints and other materials adhere to, or be indifferent toward, various solids, such as metals, quartz, earth, etc. The applications in the petroleum, food, dye and textile, and paint and lacquer industries—in fact in practically every industry—are so varied and new, and so specific for different small classes of these new materials, that few have yet found their way into published literature.

Colloidal electrolytes include a vast number of substances in which extreme surface activity in very dilute solution and ability to conduct colloidal particles in higher concentrations play a dominant role, which not only makes them of great interest in themselves, but gives them a most varied usefulness in all branches of applied science.

Applications of Electron Diffraction

LESTER H. GERMER

Bell Telephone Laboratories, New York, N. Y.

The diffraction of electrons by crystalline and pseudocrystalline substances has become a method of procedure for various chemical and physical investigations. Electron diffraction is thus an immediate "practical" application of the wave nature of matter. This is a position which it shares with the electron microscope, although the latter would probably have been invented independently of wave mechanics, and its present technical development would not have led to the discovery of electron waves.

The effectiveness of the electron diffraction method in obtaining desired information can be judged from the fact that it is being used in this country in thirty or forty laboratories, divided about evenly between educational and industrial institutions. Much of the electron diffraction work of these laboratories has been published in about 300 scientific papers, and about 700 papers have been published dealing with similar work carried out in foreign laboratories.

Of all these investigations, many are pioneer studies connected with the discovery of the diffraction of electrons and with the observation of the phenomenon under various conditions; others, and especially the more recent investigations, are more properly the application of the electron diffraction technique to various problems of more or less immediate and practical importance. Researches of the latter type only will be considered here. Since, furthermore, there exist comprehensive summaries of the literature on the subject, it seems undesirable to include any extensive bibliography or any account of more than a very few of the researches which have been made.¹ This paper will deal first very briefly with the fundamentals of the experimental technique; then with a consideration of the fields of usefulness of electron diffraction; and finally with some selected researches upon the structure of exceedingly small particles and exceedingly thin films.

Experimental Method

It is customary to produce electron diffraction patterns by the scattering of a beam of electrons of uniform speed. The speed, v , determines the electron wavelength, λ , through the de Broglie formula $\lambda = h/mv$, and the wave-length usually employed is of the order of 5×10^{-10} cm corresponding to electrons which have been accelerated by a potential difference of about 50 kv. The electrons of the primary beam must receive this acceleration in a vacuum chamber. After acceleration and collimation, the electron beam is scattered by the experimental specimen and the diffraction pattern of the specimen is recorded on a photographic plate placed perhaps 50 cm from it and normal to the beam. The evacuated chamber in which the electrons are produced, accelerated, collimated, scattered and recorded is commonly called an electron diffraction camera. It is attached to vacuum pumps, and is equipped with means for adjusting the specimen and the photographic plate while the camera is exhausted.

FIGURE 1. Electron diffraction camera used in the Bell Telephone Laboratories.

A photograph of the camera used in the Bell Telephone Laboratories appears as Figure 1, and a description of an earlier model of this apparatus was published several years ago.² Most experimenters have built their own cameras and many of these have been described in the literature (see, for example, the bibliography of Thomson and Cochrane¹). Since an electron microscope can be modified to function as a diffraction camera,³ this type of equipment may become widely used.

Fields of Usefulness of Electron Diffraction

Electron diffraction has been applied to the determination of the arrangement of atoms both in molecules in the gaseous state and in solid bodies. Although the

former is the more systematically developed field of usefulness,⁴ it will not be considered here. We shall be concerned only with the diffraction of electrons by solid bodies, or rather with conclusions regarding the structure of solid bodies which can be drawn from the way in which they diffract electrons.

The atomic structure of solid bodies is precisely the type of information obtained by the methods of x-ray diffraction. Yet, because x-rays are very penetrating, and because electrons of the speeds commonly used are strongly scattered and thus penetrate very slightly, the fields of usefulness of the two techniques do not greatly overlap. If one attempts to describe the weakening of a primary beam of electrons of 50 kv equivalent speed in a mica crystal by means of an absorption coefficient, μ , one obtains⁵: $\mu \sim 2 \times 10^6 \text{ cm}^{-1}$. For heavy metals it would be considerably larger. In empirically useful language, one can state that information regarding the structure of a substance made up predominantly of heavy atoms (atomic number of the order of 75) can be obtained only when the experimental conditions are such that the path of the electrons in the substance is considerably less than 10^{-5} cm in length. Suitable upper limits for length of path vary from about 500 Å for gold to 2000 Å for magnesium.

From these estimates of penetrating power it is clear that electron diffraction can be used to investigate only the structure of extremely thin films and extremely thin surface layers. Thus its field of usefulness is limited, but it is limited to a region which is in many cases of great fundamental and practical interest and which cannot be so adequately studied by any other known method.

Within its restricted field electron diffraction can be put to various uses. The most widely developed of these, leaving out of account investigations of the structure of gaseous molecules, is in microchemical analysis. An electron diffraction pattern from a solid block is characteristic of the substance at its surface. Comparison of the pattern from an unknown substance on the surface of a block with patterns obtained from known substances can enable one to identify the unknown. For this type of analysis to be effective, it is necessary that patterns from a large number of substances be observed and recorded in accessible form. A tabulation of the crystal spacings, and relative intensities of the corresponding reflections, for 1000 substances in powder form has been published by Hanawalt, Rinn and Frevel.⁶ A committee of the National Research Council, under the direction of Dr. Wheeler P. Davey of Pennsylvania State College, is engaged in assembling and publishing sets of spacings for a larger number of compounds. The actual structures are available⁷ for many compounds for which powder patterns happen never to have been recorded; identification of one of these appearing as an unknown substance at the surface of a block can frequently be made, although not so readily as if the powder pattern data were available.

This method of chemical identification by means of an electron diffraction pattern is similar to identification from an x-ray pattern. Either diffraction method yields more detailed information than any other analytical procedure; it determines not only what chemical elements are present but also just how they are combined, and, if the crystal structure of the substance is already known, precisely how the atoms are arranged in the crystals. In addition, either method will in general give a great deal of information in regard to the crystals themselves: information in regard to their average size; whether or not they are randomly oriented and, if not, quantitative data on the distribution in orientation; whether or not the crystals are seriously strained; even in some cases data regarding their shapes.

Since an x-ray pattern is produced by the body of a block and an electron pattern by its surface layers only, in some cases only the former yields useful information, and in other cases only the latter. In many instances the two diffraction patterns are characteristic of different compounds, or the same compounds in different proportions, and the patterns supplement each other; both are necessary for the knowledge

desired. As an illustration of the need for both types of analysis, one can cite studies of the oxidation and reduction of iron under conditions which are industrially important. For example, the electron diffraction pattern of Figure 2 from the surface

FIGURE 2. Electron diffraction pattern of Fe_2O_3 obtained from the surface of an iron plate.

of an iron plate can be identified as due entirely to the oxide Fe_2O_3 , but the strongest lines of an x-ray pattern from this plate are those of Fe_3O_4 , with weaker lines of iron and still weaker lines of Fe_2O_3 . From the two patterns one can conclude that the iron was covered by a layer of Fe_3O_4 about 10^{-3} cm thick, on the surface of which was a 10^{-4} -cm layer of Fe_2O_3 .

In the analysis of an unknown substance from its x-ray pattern the identification can be greatly aided by a supplementary spectroscopic analysis to determine the chemical elements which are present. In fact, in a laboratory where such analyses are frequently made it may be the usual procedure to make the spectroscopic analysis first, and to follow this by the x-ray analysis. On the other hand, identification from electron patterns cannot in general be aided by spectroscopic analysis. The surface layers which produce the electron patterns are frequently too thin to permit a spectroscopic analysis; if they were *not* too thin, then probably the x-ray method would be applicable; the latter is always more convenient if the layer to be studied is sufficiently thick. Because of technical difficulties such as those arising from an unfavorable surface contour of the specimen, and because aid cannot, in all cases at least, be obtained from spectroscopic or ordinary microchemical analysis, identification of a surface film from its electron diffraction pattern is in general more difficult than the identification of the bulk material from its x-ray pattern. Yet the electron diffraction method is being widely used in industrial laboratories and elsewhere for the identification of surface films because of the precise knowledge which it is capable of giving and because in a great many cases there is no other available method.

Although microchemical analysis of surface layers is at the present time the most widely developed use of electron diffraction from solid bodies, analyses of this sort are not the subject of the bulk of the papers on electron diffraction, nor is microchemical analysis as such by any means the most interesting application. Others are extremely diverse and poorly systematized, but they seem at present to offer potentialities of great future development.

One thinks at once of using electron diffraction to get information about catalytic processes. Although catalytically active surfaces are being studied by electron diffraction in some industrial laboratories, one cannot judge how extensive and how successful this work is because very few of the results have been published.⁸

From a great number of diverse applications of electron diffraction I have chosen to describe here three which have to do with particles of sub-colloidal dimensions, or with films only a few molecules thick. The choice was arbitrary and was dictated by familiarity with the researches. These studies can perhaps be thought of as belonging to a branch of science appropriately described as surface chemistry or surface physics. Thought of in this way, they are representative of the most interesting, and although the least well developed perhaps ultimately the most important of the uses which can be made of electron diffraction. They illustrate furthermore the extreme sensitivity of the method in its application to very small amounts of material.

Electron Diffraction Studies

Diffraction of Electrons by Small Crystals.⁹ By using an extremely thin organic foil as a support, very small amounts of various elements and inorganic compounds have been studied by electron diffraction by the transmission method. With a foil as thin as 100 Å the electron scattering from the foil makes an inappreciable addition to the scattering pattern from a deposited layer of heavy metal atoms as thick or thicker on the average than two or three atomic layers. The method is therefore adaptable to the determination of the arrangement of atoms in exceedingly thin films.

In one series of experiments diffraction patterns have been obtained from films of widely different mean thicknesses and of various substances deposited in vacuum upon a Formvar supporting foil by vaporization from a tungsten ribbon. A pattern from a cesium iodide film of 30 Å mean thickness is shown in Figure 3. From esti-

FIGURE 3. Diffraction pattern from a film of cesium iodide of 30 Å mean thickness.

mated breadths at half maximum ΔR of the rings of this pattern, one can calculate the mean crystal size C by means of the well-known Scherrer formula, which can be written in the form $C = L\lambda/\Delta R$, where $L\lambda$ is the product of the specimen-plate distance and the electron wave-length. In this manner one determines that the crystals of cesium iodide in this film have average linear dimensions of about 200 Å. This value, together with the fact that the amount of deposited material was sufficient to form a layer only 30 Å thick on the average, leads to the inevitable conclusion that, under the conditions of formation of the film, the molecules are unstable when spread out uniformly, and that they cluster at once into quite large crystals.

Somewhat similar deductions have been made regarding conditions of stability in films of many different substances, although in many cases the mean crystal size has been found to be much smaller than 200 Å. In particular, metal atoms in general form smaller crystals than do molecules of most inorganic compounds which have been investigated.

A rather extensive study of copper films has been carried out, the metal in these experiments being vaporized upon supporting Formvar foils within the diffraction camera itself in order that in each test a diffraction pattern could be obtained without exposing the freshly prepared film to oxidation in the air. The films of copper studied have had various mean thicknesses, the greatest being 780 Å, and the least 3 Å, which is only slightly larger than the diameter of a copper atom. All films

thicker than 20 Å produce diffraction patterns characteristic of the face-centered cubic structure in which copper crystallizes. The sharpness of the rings varies somewhat from one pattern to another, the rings of the patterns from the thicker films being narrower than those of the patterns from the thinner films. This variation of sharpness arises from differences in mean crystal size in the different films, the calculated size varying from about 70 Å in the thickest films to 50 Å in 20-Å films. It is clear in the first place that crystals are never larger than 70 Å no matter how thick the film, and in the second place that in films as thin as 20 Å the originally uniform distribution of atoms is unstable, and they draw together to make 50-Å crystals.

Diffraction patterns from films thinner than 20 Å appear at first to be qualitatively different. The rings are not only broader than those from thicker films, but they appear to be altered in relative intensity, so that a pattern can no longer be recognized as that of face-centered cubic crystals. The interpretation of this is quite simple. A spherical crystal of copper of 20 Å diameter contains somewhat less than 400 atoms. The resolving power of crystals of this size is sufficiently good so that a resulting powder pattern will be readily recognized as that of face-centered cubic crystals. If, however, the number of atoms in the individual crystals is much less than 400, the resolving power will be so poor that the characteristic "face-centered cubic reflections" are no longer distinguishable. In Figure 4 are given calculated scattering curves for randomly oriented spherical or near-spherical face-centered cubic crystals containing various small numbers of atoms. (In order that these curves shall be applicable to crystals of different metals, the atomic scattering factor of copper has not been included in the calculation; this would introduce a factor which is continuously decreasing with increasing angle.) The locations, Miller indices, and relative intensities of reflections from extended face-centered cubic crystals are indicated at the bottom of the figure. By comparing these with the calculated scattering curves above, it is clear that crystals containing 379 atoms each will produce a pattern from which the face-centered cubic arrangement of atoms can be readily deduced, but that crystals of 55 atoms each, or any smaller number, cannot be interpreted in this manner. It would certainly be utterly impossible to interpret an experimentally observed pattern like the calculated pattern for 55-atom crystals, unless one had independent reasons for suspecting a face-centered cubic structure.

When the electron scattering pattern from the film of copper of 3 Å mean thickness is compared with the calculated curves of Figure 4 it is discovered that the experimental pattern is intermediate in character between the curve for the 379-atom crystals and that for crystals of 55 atoms. Thus it appears clearly that the anomalous patterns obtained from extremely thin copper films are accounted for by the small number of atoms in the individual crystals and their resulting poor resolving power. It is possible to estimate from the *character* of the pattern from the 3 Å film that the individual crystals contain on the average about 200 atoms and that they are more or less equi-axed. Thus, for this thinnest film also, the originally uniformly distributed layer of atoms is unstable and crystals of appreciable dimensions are formed. For such excessively small crystals the *character* of the scattering pattern gives a quantitative measure of mean size, which is a considerable extension of the range of crystal size which can be determined.

Arrangement of Molecules in Monolayers and Multilayers. Layers of various long-chain organic molecules can be built upon the surface of a block, one layer at a time, by the well-known Langmuir-Blodgett technique, in which molecules in a single layer floating upon water are transferred to the block when it moves through the water surface. Electron diffraction patterns of such built-up layers of molecules yield information regarding the structure of the layers. The patterns are simple and readily interpreted, because in each molecule the separation between alternate carbon atoms is repeated over and over, because the carbon atoms of each molecule are coplanar, and because the molecules of any one layer align themselves with their

axes parallel. The information regarding the structure of these built-up layers of long molecules is of interest in itself; but perhaps of more importance is the ex-

FIGURE 4. Theoretical scattering curves from randomly oriented face-centered cubic crystals made up of various numbers of atoms.

perience which experimenters have gained by interpreting these patterns. This has enabled them to attack successfully diffraction patterns of surface films made up of organic molecules having less simple shapes, although the latter investigations are still of a rather rudimentary character. It will suffice here to reproduce patterns obtained from a few layers of long-chain molecules, to indicate how these patterns

are interpreted, and to state conclusions drawn from a systematic study of built-up films containing various numbers of layers of two simple organic molecules.¹⁰

The diffraction patterns of Figure 5 were produced respectively by a single layer of barium stearate molecules upon the surface of a metal block, and by three layers

FIGURE 5. Diffraction patterns from barium stearate.

A. A single layer of molecules.

B. Three layers of molecules.

of molecules. The separation, R , between the diffuse vertical bands of these patterns corresponds by the Bragg formula, which can be written $Rd = L\lambda$, to a spacing $d = 2.50$ Å, repeated many times in a direction normal to the surface; observation of this spacing is conclusive proof that the bands are due to hydrocarbon chains standing perpendicular to the surface. The distribution of scattering intensity is markedly different along the bands of even order from that along the bands of odd order. This difference arises from the zig-zag nature of the chains and from the

fact that all the carbon atoms of each chain lie in one plane. The diffraction features lying upon the bands of Figure 5B are produced by regularities in the lateral arrangement of the molecules, and it is easy to calculate, from the positions of these features, that the molecules are built into a number of structures in each of which the axes of the molecules intersect the corner-points of an extended, two-dimensional, close-packed hexagonal net lying parallel to the surface, the side of the net being 4.85 Å. From the absence of any diffraction features on the bands of the pattern of Figure 5A we must conclude that, in the first layer of barium stearate molecules upon the surface, there is no regularity of lateral arrangement; in the first layer the molecules are packed closely together but without definite regularity.

Electron diffraction patterns produced by stearic acid molecules built upon a metal surface show some similarities to patterns from barium stearate molecules, but there are also differences. The stearic acid molecules produce diffuse bands corresponding to the same separation of 2.50 Å; but, whereas stearic acid molecules in the first layer stand normal to the supporting surface as do the molecules of barium stearate, in the second and subsequent layers stearic acid molecules stand with their axes inclined to the surface. The inclination to the surface is always by a definite angle which lies in the plane that was vertical when the block was dipped through the water surface. The stearic acid molecules of all layers except the first are built, furthermore, into true crystals having monoclinic symmetry. Some significant parameters of these crystals can be determined, and these parameters agree with previous knowledge of stearic acid crystals and extend such knowledge.

It is interesting to note the differences between the soap or acid molecules of the first layer and similar molecules in layers beyond the first. Molecules which touch the metal surface stand normal to it and do not possess any regularity in their lateral arrangement; but in subsequent layers molecules are built into compact crystalline arrays determined by the habit of the substances in bulk. The simplest interpretation seems to be chemical attraction between the surface and the metal atoms of the soap or the carboxyl groups of the acid, this attraction being strong enough to hold the first layer of molecules fast in certain positions, which are determined by the surface atoms rather than by the natural habit of the built-up layers.

This interpretation is supported by a series of electron diffraction experiments upon built-up layers which have been rubbed. Rather light rubbing takes off all except the first layer of barium stearate or stearic acid molecules; but the first layer is exceedingly resistant to removal by rubbing with material which does not abrade the underlying metal itself. It is possible by extremely light rubbing in one direction to "upset" stearic acid molecules of all layers except the first, so that they then lie with their axes nearly, but not quite, parallel to the surface. In this condition the molecules are moderately resistant to continual light rubbing in the same direction, but they are removed by almost the lightest possible rub in the opposite direction.

The Structure of Black Carbon.¹¹ Electron diffraction studies of what was formerly called amorphous carbon have made significant additions to our knowledge of its structure. The most informative of these studies have been carried out upon carbon deposited upon quartz blocks by pyrolysis of methane. The resulting carbon films are found in many cases to exhibit marked preferential orientation, and it is to this orientation that the ease of interpretation of the unusual diffraction patterns must be attributed. These patterns are more readily interpreted than those from randomly oriented carbon having the same structure, for the reason that a diffraction pattern from a single crystal, which is being rotated about an important crystal direction, can yield more information than a Debye-Scherrer pattern from many small crystals.

In Figure 6 is reproduced one of the electron diffraction patterns from pyrolytically deposited carbon having very strong orientation. The uniformly spaced, heavy, diffuse spots along the horizontal center line correspond to a separation of

6.66 Å normal to the surface of the supporting block. This distance is about 9 per cent greater than the separation between adjacent hexagonal planes in graphite, and from the result of this comparison it is natural to infer that the pattern of Figure 6 was produced by graphite-like crystallites oriented with their hexagonal planes predominantly parallel to the supporting quartz surface.

Along the vertical line at the shadow edge one can find on the original plate 5

FIGURE 6. Diffraction pattern from very small oriented pseudo-crystals of black carbon.

pairs of diffraction features having radii which are proportional, as closely as they can be measured, to the square roots of the integers 1, 3, 4, 7 and 9. These ratios are just those of $(h k o)$ reflections from graphite crystallites, and the separation between atoms turns out to be 2.46 Å, which is just that between atoms in the hexagonal planes of graphite. Yet the relative intensities of these reflections are not those to be expected from graphite. It is easy to discover that the intensities correspond to reflections from parallel, but otherwise utterly unrelated, planes of carbon atoms, in each of which the atoms are arranged as in the basal plane of graphite. The intensities are quite different, on the one hand from what they would be if the planes of atoms were built into true graphite crystals, and on the other hand from what they would be if the atoms in the parallel, but otherwise unrelated, planes had a close-packed arrangement (*e.g.*, the atoms in the hexagonal planes of magnesium or zinc). This deduction from the intensities of the $(h k o)$ reflections is borne out by the fact that no trace whatever can be discovered of any general reflections of the type $(h k l)$.

These two sets of diffraction features on the pattern of Figure 6 lead thus to a fairly clear qualitative picture of the structure of the carbon film: It is made up of sharply oriented pseudo-crystals in each of which the atoms are arranged in hexagonal planes which are exactly like those of graphite. In each pseudo-crystal these planes are parallel and equi-spaced by distances about 9 per cent greater than corresponding planes in graphite. Yet there are no regularities in the lateral positions of planes belonging to the same crystallite, and they are therefore not true crystals at all.

These deductions, which can be made in such a very simple manner, are sub-

stantiated by transmission patterns produced by electrons which have passed *through* similar films of carbon, as well as by a more penetrating analysis of the pattern of Figure 6. This more detailed analysis, which will not be given here, leads also to quantitative values for average dimensions of the pseudo-crystals and to a mathematical expression representing approximately the law of distribution of orientation of the individual pseudo-crystals about the surface normal. The average dimensions discovered in this manner are very small—rather astonishingly small in fact. Parallel to the hexagonal planes it is found that the average dimension is 20 Å, or about 5 unit hexagons, and normal to these planes it is 10 or 15 Å, or 3 or 4 layers of atoms.

This structure represents the most degenerate form of pseudo-graphitic carbon. Previous x-ray investigations had revealed an extended series of carbon starting with graphite and having progressively less regular structures. By an extrapolation process in this series of x-ray studies an inferred structure had been previously assigned to this very degenerate carbon. Although this postulated structure agrees with that ascertained in the present investigation, the electron diffraction studies give the first reliable proof of the true structure.

These three researches were chosen for mention here primarily because they illustrate the extreme sensitivity and delicacy of the electron diffraction technique. Each of these studies was concerned with the structure of units of matter so very small that their dimensions are given in terms of atom diameters or of lengths of molecules more appropriately than in ordinary units of length. Many investigations have been carried out in this sub-colloidal region, but the possibilities are still scarcely realized.

Methods for the Analysis of Complex Molecular Structures with the Aid of X-Rays

MAURICE L. HUGGINS

Eastman Kodak Company, Rochester, N. Y.

The analysis of a complex structure with the aid of x-rays is possible only if the structure is composed of many like (or very similar) units, repeated at uniform intervals. A few very large virus molecules may have internal structures which satisfy this requirement, but in general it is satisfied only by crystalline aggregations of many molecules. In any case, the problem is essentially that of determining the structure of a complicated *crystal*, and so we shall treat it here. At best, this is not a simple problem and one cannot expect, without a prohibitive amount of labor, to deduce accurately the relative positions of all of the atoms in really complex structures. Yet the general methods of procedure have now been developed to such a degree that much more can be accomplished in this direction than a few years ago, and there is every reason to expect further progress in the future.

The aim of this paper is to outline the general procedures now in use for complex structure analyses. For details, one must of course go to other sources.^{6, 8, 22}

Outline of Structure Analysis Methods

When a beam of x-rays impinges on a crystal, diffracted beams are produced in many directions. Each beam is customarily designated by a set of three indices ($h\ k\ l$) which give the orientation in the crystal of a set of parallel planes which may be visualized as "reflecting" that beam. (The indices are integers, proportional to the reciprocals of the intercepts of each reflecting plane on the crystal axes, these intercepts being measured as fractions or multiples of the unit distances.) Given a large number of reflections, the crystal structure analyst determines, by procedures we shall not take space to discuss, the smallest unit cell, consistent with the external symmetry of the crystal, which will account for these reflections—that is, the smallest cell, on the basis of which integral indices can be assigned to all the reflections observed.

When the dimensions of the unit cell have been determined, the numbers of molecules and of atoms of each kind that it contains are readily computed from the chemical formula of the substance, the atomic weights, and the density.

A considerable amount of information about the internal symmetry of the crystal—the existence and spatial distribution in the unit cell of centers, planes and axes of symmetry—can be obtained from a study of the indices of the observed reflections, noting classes of reflections (*e.g.*, those having all indices odd) which are entirely absent, etc. Sometimes, but not always, the complete distribution of symmetry elements in the structure (the "space group") can be determined in this way, with the assistance of tables^{1, 16} of the requirements for each space group. If the correct combination of symmetry elements (space group) cannot be determined uniquely by this procedure, certain combinations can frequently be eliminated from further consideration by virtue of the fact that they will not permit any arrangement having the known numbers of atoms in the unit cell, or having the atoms grouped together

into molecules of the known chemical formula and the known or assumed molecular size, shape, and symmetry.

After as much as possible has been determined about the internal symmetry of the crystalline structure, the next step is to consider what arrangements of atoms and molecules are possible, consistent with that symmetry and with other known or assumed facts, such as the numbers of atoms of each kind per unit, the distribution of these atoms into molecules, minimum interatomic distances, etc. With the simplest types of structures, such as those found for many inorganic substances, the exact positions of all the atomic centers are determined by the symmetry properties and dimensions of the unit cell. In slightly more complicated structures, the positions of some or all of the atoms are not so determined, but can be deduced by comparisons of relative intensities of different reflections, with or without considerations of probable or reasonable interatomic distances. For still more complicated structures, complete structure analyses can sometimes be obtained by trial-and-error methods, guided by the experimental intensity data. Once a structure has been deduced, it is of course checked by comparison between calculated and experimental intensities of the observed reflections. It must also account satisfactorily for other known physical properties of the crystals.

The relative intensities of different reflections from a crystal depend not only on the kinds and distribution of atoms in it, but also on various other factors, such as the shape of the specimen, whether it is a powder or a single crystal, the wave-length of the x-rays used, the angles between incident and reflected beams, the position of the photographic film relative to the crystal sample and the incident beam, the characteristics of the photographic emulsion, etc. In analyzing a complicated crystal structure it is useful to compute from the observed intensities, as accurately as possible, a set of "structure factor squares," F^2_{hkl} , these giving the effect of the crystal structure on the intensities, after correcting for the other factors related to the experimental technique. For any assumed distribution of atoms in the unit cell one can calculate (by addition, in a prescribed manner, of appropriate cosine and sine terms for each atom) the magnitudes of the structure factor squares to be expected and then compare these calculated values with the experimental ones.

Fourier Syntheses

If the structure is too complicated for satisfactory solution by trial-and-error methods, or if, after a partial or approximate solution, a more complete or more accurate knowledge of the structure is desired, one can add together the structure factor squares in such a way as to yield directly much useful information, as we shall see. Even more useful are summations of the structure factors themselves, in those cases for which it is possible to determine the sign of each.

The structure factor is the product of a (positive) amplitude factor and a complex phase factor, the latter being undeterminable directly from the experimental data. If the structure has a center of symmetry at the origin of coördinates (any corner of the unit cell), the phase factor must have the value $+1$ or -1 . The magnitude of the structure factor can then be obtained by taking the square root of the corresponding structure factor square. Its sign remains unknown, unless one has some information about the structure, other than that embodied in the experimental F^2 values. If the positions of the heavier atoms (those having the greatest scattering power for x-rays) in the unit cell are approximately known, the signs of all the more important structure factors can be computed with sufficient certainty. For example, if it is known that most of the electrons in the unit cell are concentrated in a single atom, having its center at a center of symmetry, one can choose the origin there; the signs of all the structure factors (or at least all of those not having very large indices) are then positive.

Knowing the magnitudes and signs of the structure factors, (ideally for all pos-

sible sets of indices, actually for all those corresponding to observed diffractions), the Fourier series summation

$$\rho_{xyz} = \frac{1}{V} \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} F_{hkl} \cos 2\pi (hx + ky + lz), \quad (1)$$

in which each structure factor is multiplied by the appropriate cosine, gives^{4, 9, 10, 12} the (time-average) electron density at the point in the unit cell having coördinates x, y, z . The V in this equation represents the volume of the unit cell. Summations for a sufficient number of points enable one to determine the atomic distribution in the unit. The center of each atom is obviously located at an electron density peak, and the higher the peak (in general) the more electrons in the atom.

As indicated in Equation 1, the electron density is given by an *infinite* Fourier series. The set of F values available experimentally being far from infinite, the results obtained from the corresponding incomplete series are in error. Error also results from inaccuracy in the experimental intensities and in the corrections involved in changing intensities to F^2 values. Fortunately, it can be shown that with reasonable care and by adopting certain procedures which we need not discuss here, the resulting errors can usually be made negligible (or nearly so), if one is interested only in the positions and identification of the atoms in the structure and not in the exact electron distribution within each atom and between the atoms.

To cover the complete unit cell thoroughly in the way just outlined would take a great deal of time and labor, but this can be obviated by certain modifications of the procedure. The desired information can frequently be obtained by computing the electron density only for certain planes or along certain lines cutting through the unit cell. For example, the density distribution in the XY plane (the face of the unit parallelepiped which includes the X and Y axes) is given by the equation

$$\rho_{xy0} = \frac{1}{V} \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} F_{hkl} \cos 2\pi (hx + ky) \quad (2a)$$

$$= \frac{1}{V} \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} G_{hk} \cos 2\pi (hx + ky) \quad (2b)$$

where

$$G_{hk} = \sum_{l=-\infty}^{\infty} F_{hkl} \quad (2c)$$

Likewise, the density along the X axis is given by

$$\rho_{x00} = \frac{1}{V} \sum_{h=-\infty}^{\infty} H_h \cos 2\pi (hx), \quad (3a)$$

where

$$H_h = \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} F_{hkl} \quad (3b)$$

In practical structure analysis, two-dimensional summations,⁴ including only terms for reflections corresponding to planes in certain zones (e.g., only $h k 0$ reflec-

A. A little more than the unit cell of the structure. This same electron distribution would be obtained by calculating the electron density, using Equation 1, at a sufficient number of points.

B. Electron distribution in the XY plane ($z=0$). This would be obtained by the application of Equation 2. (For this structure, the distribution in the XZ or YZ plane is exactly the same.)

C. Electron distribution along the X axis ($y=z=0$), obtainable by Equation 3. (The distribution along the Y or Z axis would be the same).

D. Electron distribution along the cube diagonal ($x=y=z$). (The distribution along each of the other cube diagonals would be the same).

FIGURE 1. Electron distribution in a simple hypothetical crystal structure. Atoms are assumed to be points with scattering powers equal to the numbers of electrons given in the circles.

tions), are more frequently used. Such a summation yields a projection of the electron density in the unit cell onto a plane normal to the zone axis. For instance,

$$\rho_{xy} = \frac{1}{A} \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} F_{hko} \cos 2\pi (hx + ky) \quad (4)$$

gives a projection of the electron density (parallel to the Z axis) onto the XY plane. A is the area of the projection of the unit cell, in this case equal to the area of the XY face of the unit cell. With such a projection for each of the three axial planes (XY , XZ , YZ) the complete distribution of atoms in a structure can be determined, at least theoretically.

One-dimensional summations,⁹ giving projections of the unit cell onto a line through it, are also useful. For a projection onto the X axis, the equation is

$$\rho_x = \frac{1}{L} \sum_{h=-\infty}^{\infty} F_{h00} \cos 2\pi (hx) \quad (5)$$

L is the length of the projection of the unit cell, in this case equal to the unit distance (a_0) in the X direction.

FIGURE 2. Projections of the electron distribution in the hypothetical structure of Figure 1A.

Figures 1 and 2 show what would be obtained ideally, using infinite series and absolutely accurate data, from a simple hypothetical structure (Figure 1A) consisting of point atoms. In an actual case, the atoms show up as peaks (rather than points) of electron density. The projections and sections are therefore represented as contour maps. Figures 6B and 9C are typical examples.

If enough is known about the structure from a preliminary trial-and-error analysis to make possible the determination of the signs of the structure factors (assuming the structure to have a center of symmetry) for the more intense reflections, a summation including only terms corresponding to these more intense reflections may enable one to obtain the signs of the structure factors for additional

reflections and so, by successive approximations, to arrive at the final detailed structure.

The following summations, which are like those of Equations 1 to 5 inclusive except for the replacement of F_{hkl} by F^2_{hkl} and the omission of the $\frac{1}{V}$, $\frac{1}{A}$ and $\frac{1}{L}$ factors, are also useful.

$$P_{xyz} = \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} F^2_{hkl} \cos 2\pi (hx + ky + lz) \quad (6)$$

$$P_{xy0} = \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} F^2_{hkl} \cos 2\pi (hx + ky) \quad (7a)$$

$$= \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} G'_{hk} \cos 2\pi (hx + ky) \quad (7b)$$

$$G'_{hk} = \sum_{l=-\infty}^{\infty} F^2_{hkl} \quad (7c)$$

$$P_{x00} = \sum_{h=-\infty}^{\infty} H'_h \cos 2\pi (hx) \quad (8a)$$

$$H'_h = \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} F^2_{hkl} \quad (8b)$$

$$P_{xy} = \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} F^2_{h00} \cos 2\pi (hx + ky) \quad (9)$$

$$P_x = \sum_{h=-\infty}^{\infty} F^2_{h00} \cos 2\pi (hx) \quad (10)$$

They require no knowledge of the phases and so no preliminary knowledge of the structure. Such summations have been shown by Patterson²⁰ and Harker¹¹ to yield "vector structures"²⁰ and projections²⁰ and sections¹¹ of such structures (Figures 3 and 5), from which one can deduce the principal interatomic distances and directions in the structure. This knowledge may suffice to determine the phases of the reflections for electron density summations or to enable the complete structure to be worked out in other ways.

The physical meaning of the Patterson summations can be explained by reference to Figure 4. In this figure, *a* represents a distribution of point atoms along a line. In *b*, all the vectors from each atom in the unit to each atom (including itself) in the unit are represented, each vector terminus being given a weight equal to the product of the numbers of electrons in the atoms at the two ends of the vector. In order to show these vectors individually, the lines representing them are here separated by shifting them vertically with respect to each other. In *c*, these vectors are all shifted horizontally, so as to make their origins coincide, except for the vertical displacement. Without this vertical displacement, the result is as indicated by the heavy line (and the circles it connects) in *d*. (If two vectors terminate at the same point, their weights are added.) These circles represent the Patterson

summation for a single unit cell. Similar summations for neighboring unit cells are also shown (with vertical displacement) in *d*. Adding these together gives *e*, representing the complete Patterson structure corresponding to *a*.

Since atoms are actually distributed over finite volumes, with continuously varying (time-average) electron densities, the straight addition of vectors just described is replaced by an integration and each vector has a weight equal to the product of the electron densities at its ends.

Two- and three-dimensional Patterson vector structures are related to the two- and three-dimensional electron structures in the same way as in the one-dimensional case, except that the vectors are no longer all oriented along a line. Comparison of Figures 3A and 3B with Figures 1A and 1B should make this relationship clear. An example of a Patterson-Harker section, obtained by means of Equation 7, is shown in Figure 9D.

FIGURE 6A. Potassium dihydrogen phosphate (KH_2PO_4). Distribution of atomic centers in the unit cell. Large open circles represent potassium; filled circles, phosphorus; small open circles, oxygen.

An instructive comparison is shown in Figures 6A, 6B and 6C. 6A depicts the unit cell of the crystal structure of potassium dihydrogen phosphate, KH_2PO_4 , deduced approximately by Hendricks,¹³ using trial-and-error methods and, more accurately, by West²⁴ using Fourier summations. Figure 6B shows a contour map, obtained by West, representing the electron density projection onto the *XY* plane. This was made from the experimental *F* values, using Equation 4, the signs being determined for the most important reflections from the knowledge of the approximate atomic positions gained from the trial-and-error analysis and for the less important reflections by successive approximations. Figure 6C shows the corresponding Patterson projection.²⁰ Although this does not show what the structure would look like if we could see it, it does show certain facts about the relative positions of the atoms which (if the structure were not already known) would be of great help in working out further details—in checking hypotheses regarding the structure, etc.

A prohibitive amount of time would be required to make, by straight numerical calculation, three-dimensional summations, of the sort represented by Equation 1 or Equation 6, for points distributed at small intervals throughout the unit cell. Direct three-dimensional summations are only feasible for the calculation of electron

FIGURE 6B. Potassium dihydrogen phosphate (KH_2PO_4). Contour map,²⁴ representing the electron density projection onto the XY plane, calculated from experimental F_{hko} values by Equation 4.

densities or vector densities in specific planes (Equations 2 and 7), along certain lines (Equations 3 and 8), or at a few strategic points. Two-dimensional projections (Equations 4 and 9) have, so far, proved much more generally useful. Even they, however, require long tedious computation, if made by direct summations. Some very useful simplifications, taking advantage of such symmetry elements as the structure may possess, have been introduced. Various devices,^{3, 19, 21} such as sets of strips, each giving sines or cosines (at uniform intervals of one coördinate) for a given index and a given F (or F^2) value, have been introduced to reduce still further the computational time and the chance of error. Even with these, calcula-

tions for a satisfactory two-dimensional projection or section of a complex structure are long and tedious, requiring many hours, usually days.

Four different types of method have been proposed and tried out for making the summations more automatic and (if possible) faster. One^{2, 23} involves the use of previously prepared sets of tens of thousands of punched cards, from which the particular cards representing the individual terms in the series are chosen and fed into the proper computing machines according to an established routine. This pro-

FIGURE 7. Reciprocal lattice level ($l=0$) for a cubic crystal.

cedure undoubtedly will give accurate, reliable results (from good data) and will save some time, once the machines have been bought or rented and suitably wired, the sets of cards have been prepared, and the proper sequence of operations has been learned.

Macewan and Beever¹⁸ have recently described a very different type of machine, utilizing standard commercial telephone equipment, for rapid Fourier summations. This type of machine shows promise of being very useful.

The third type of method was first proposed and tried by W. L. Bragg.⁷ The layer of the reciprocal lattice (Figure 7) corresponding to the summation desired is laid out on a thin, opaque plate (say, of brass) of suitable size, using a scale which will permit inclusion of reciprocal lattice points having the same indices as those for the terms to be used in the summation. At each reciprocal lattice point a hole is drilled having an area proportional to the structure factor. If an electron density

summation is desired, or to the square of the structure factor, if a Patterson summation is to be made. The perforated plate is then bathed in a beam of monochromatic parallel light (from a point source at the focus of a lens in front of the plate) and the light which passes through the holes is focused by a second lens onto a photographic film. The interaction of the rays passing through the holes in the plate produces a photograph which reproduces, within certain limitations, the electron density or vector density distribution in the structure.

For electron density summations this method can be used only if the structure factors all have the same phase (*i.e.*, if the projection has a center of symmetry and the signs of the structure factors are all positive). Buerger⁸ has proposed a scheme for making this method usable for any centrosymmetrical projection. The perforated plate is placed between crossed Polaroid films, and each hole in the plate is covered with a small piece of mica or strip of Polaroid film. These strips are oriented with their vibration directions parallel to a certain direction for positive structure factors and perpendicular to this direction for negative structure factors. Although theoretically possible, the practical difficulties are great—especially the necessity for keeping the optical thickness of each of the Polaroid sheets and of the whole set of Polaroid strips or sheets of mica uniform to within a small fraction of the wavelength of the light throughout the whole cross-section of the beam. It will be a tribute to Professor Buerger's ingenuity and technical skill if he is able to overcome these difficulties.

Buerger has also proposed that one use, instead of a brass plate in which tiny holes are bored, a print (on transparent film) from an x-ray diffraction photograph made by the de Jong and Bouman method. On such a photograph the spots are distributed as are the reciprocal lattice points, the blackening of each spot being produced by an x-ray intensity proportional to $|F_{hkl}|^2$ times certain other factors which he proposes to correct for by means of suitable rotating sectors. Then, by careful control, he should be able to obtain a print which will let light through a transparent spot at each lattice point, in an amount which is proportional to the value of F^2 for that point. This procedure should eliminate the necessity of measuring a large number of individual intensities before proceeding with a Patterson projection.

The fourth new type of method of more-automatic synthesis of Fourier projections and sections is also due to W. L. Bragg.^{5, 6} Certain modifications of Bragg's experimental technique have been proposed by Hettich¹⁴ and by Huggins.¹⁵ According to Huggins' scheme, two masks are made, once for all, for each pair of indices (*e.g.*, hk). One mask is used when the structure factor is positive, the other when it is negative. Each mask is crossed by light and dark bands (Figure 8), in such a way that the amount of light energy transmitted in a given time is proportional to $1 + \cos 2\pi(hx + ky)$ for a positive structure factor, or $1 - \cos 2\pi(hx + ky)$ for a negative structure factor. In making an *electron density* projection, successive exposures are made through those masks corresponding (in h , k and *sign*) to the structure factor data being used, the times of exposure being proportional to the magnitudes of the structure factors. If a *Patterson* projection is desired, only "positive" masks are used and the exposure times are proportional to the structure factor *squares*. For maps of the electron density or vector density distribution within a given plane in the structure, the exposure times and "signs" of the masks are determined by Equation 2c or Equation 7c or another similar equation (for a differently oriented plane).

The total intensity striking the film or paper on which the synthesis is being made is proportional (for an electron density projection) to

$$\sum |F_{hko}| + \sum F_{hko} \cos 2\pi(hx + ky),$$

the second summation being that desired and the first an unwanted background. A suitable choice of photographic film or paper enables one to eliminate this background almost completely.

A photograph, obtained in this way with the aid of a preliminary set of masks, is shown in Figure 9b. It represents the electron density in a portion of the unit cell

FIGURE 8. Mask ¹⁵ for optical Fourier synthesis of two-dimensional projections and sections (Equations 2, 4, 7, 9).

FIGURE 9A. Pentaerythritol, $C(CH_2OH)_4$. Distribution of atomic centers in the unit cell. Open circles denote oxygen; filled circles, carbon. Hydrogens are not shown.

FIGURE 9B. Pentaerythritol. Projection onto the XY plane. The lower half of the figure contains a photographic representation of the electron density distribution, obtained by optical Fourier synthesis; the upper half shows only the relative positions of the atomic centers.

FIGURE 9C. Pentaerythritol. Contour map¹⁷ representing the electron density distribution, projected onto the XY plane (Equation 4).

FIGURE 9D. Pentaerythritol. Contour map¹⁷ representing the Patterson vector structure in the XY plane.

of pentaerythritol, $C(CH_2OH)_4$, projected onto the XY plane. The F_{hko} values published by Llewellyn, Cox and Goodwin¹⁷ were used. In the same figure are shown the positions of the atomic centers in the remainder of the unit of the projection. Figure 9A gives the atomic distribution within the whole unit cell. Figures 9C and 9D are reproductions of contour maps, published by the above-mentioned authors, representing the electron density distribution projected onto the XY plane (Equation 4) and the Patterson vector structure in this same plane (Equation 7), both obtained by straight numerical summation.

The method of optical summation is very simple and rapid (most summations requiring less than an hour), once the set of masks has been prepared. It shows promise of being especially useful during the preliminary stages of a structure analysis. Although the results are of course not as accurate as those obtained by direct summation methods, with or without punched-card machines, they are probably sufficiently accurate for most purposes.

Summary and Conclusion

The customary procedure for the analysis of complex structures with the aid of x-rays has been outlined, with special emphasis on the use of Fourier series to obtain the atomic distribution more or less automatically. The very real difficulties of obtaining sufficient accurate x-ray data of the right sort for the purpose and of determining, either by trial-and-error methods or from the results of vector summations, the phases of the structure factors—the signs of the coefficients of the terms in the series giving the electron density distribution—have been slurred over. These are difficulties which must be surmounted in ways which differ greatly from structure to structure and so cannot be adequately treated in the space available here.

It should be emphasized that, even with the newer methods, analyses of complex structures take considerable time and careful, intelligent labor. Partial analyses, giving information regarding the sizes, shapes, symmetries and relative orientations of the component molecules, can be obtained relatively easily; and often such partial analyses are sufficient, in combination with information regarding the structure from other lines of investigation, to solve the problem at hand.

Microradiography of Colloidal Materials

GEORGE L. CLARK

University of Illinois, Urbana, Ill.

Any method which involves the examination and delineation of small particles, especially where magnifications are required, is properly a technique of colloid chemistry. One of these, namely, the extension to very small objects of the branch of x-ray science known as radiography, so familiar in medical diagnosis and in industrial testing of gross soundness or homogeneity of materials, has been recognized since shortly after Roentgen's discovery of x-rays. But all attempts to develop a practical and dependable method of examining very small specimens of metals, colloidal particles or biological objects for gross structure (as contrasted with determination of fine structure by x-ray diffraction) were largely unsuccessful until very recently. Several workers saw how desirable it would be to use x-rays in the preparation of photographs which would delineate, by simple differential absorption of the rays, the various phases of different composition or regions of varying density in the same material. Such a technique would correspond to photomicrography with visible or ultraviolet light, except that x-rays penetrate through a finite thickness of a specimen, whereas the photomicrograph registers only a surface of an opaque body, such as a polished and etched metal, or at best only a microtomed section of a biological specimen.

The progress in the development of ordinary diagnostic radiography exceeded the hopes of the earlier workers. Numerous developments appeared to increase the contrast (usually by impregnation) and the clarity, or detail, of the images obtained. The logical tendency of such trends inevitably led to examination of more and more minute structures, and finally to actual enlargement of the images obtained on the photographic emulsion. Since, of course, there were no lenses for enlarging the x-ray image itself before registration, such methods of enlarging the radiograph for examination have become known as "microradiography," so named because of their relationship to the parent technical field of radiography.

Technique

Although a microradiographic method was employed by Heycock and Neville in 1898¹ and by Goby in 1913,² the first work which might be considered to have biological interest was that by Dauvillier³ in 1930, who examined radiographs of vegetable cells (elder pith, etc.). The biological use of the method was extended in 1936 by Lamarque and associates⁴ in a study of plant and animal cells. All these researches, as well as those in non-biological fields, were carried out with low-voltage x-radiation using vacuum systems; for example, Lamarque used for his investigations 5000 volts on the x-ray tube with currents up to 100 milliamperes. These methods, employing soft general radiation, vacuum equipment, long exposure times, and photographic emulsions with silver halide particles too large to permit magnification of the image without loss of sharpness, were obviously subject to experimental limitations which restricted the possibilities of general use of the method. The need of a more usable method led the author and associates⁵ to develop, in 1938, a technique employing ordinary x-ray diffraction equipment, and eliminating the

necessity for a vacuum. Another essential feature was the availability of photographic film with extremely fine-grain emulsions (Gevaert Lippmann emulsion) with which enlargements up to $\times 300$ could be made without loss of detail. Characteristic radiations of suitable wave-length for most work are obtained in comparatively great intensity by working at 30,000 to 50,000 volts, using ordinary x-ray diffraction tubes with targets of molybdenum, copper, iron, cobalt, chromium, etc. The intensity of such radiations makes the use of vacuum equipment unnecessary, and permits short exposures. The radiation itself is essentially monochromatic—a factor of the utmost importance in interpretation. These methods are restricted to available target materials; it is of great advantage to have still longer wave-lengths available, but for many types of investigation this technique is certainly well adapted in its present form.

Generally, two possible methods are available for the microradiographic examination of biological materials: (a) using a technique of "absorption staining," that is, impregnating particular parts of a biological specimen with a material having higher absorption for the x-radiation employed than the normal tissue itself (like the use of barium sulfate in diagnostic radiographs of stomach and intestines); and (b) making use of the density variations in the specimen to obtain the necessary differential absorption.

To these two usual procedures may be added a third technique for highly heterogeneous materials, such as has been successfully applied by Clark and Gross⁵ to complex alloys in which several phases (each of different composition and absorbing power) may be separately delineated. In this case microradiographs are made of the same specimen with two or more effective x-ray wave-lengths, selected so that there will be a maximum difference in the linear absorption coefficients of various pairs of phases. For example, for a bronze containing copper, lead and tin, radiation from a molybdenum target (0.71 Å) will produce light areas on the print for lead, dark for tin and copper; copper radiation (1.54 Å) for the same specimen produces both lead and tin light and copper dark. Solid solutions of tin or lead appear in various shades of gray.

In any case, the sample is placed in contact with the emulsion of a very fine-grain film (Lipmann emulsion has been found to be most satisfactory, and is available either in film form or on glass plates), and irradiated with characteristic x-radiation of the proper wave-length. The film and sample may be simply wrapped in black paper or various types of cassettes may be used. On the diffraction unit a disc of film about 0.5 inch in diameter may be placed at the end of a closed tube. Into this is inserted a closely fitting smaller tube, covered at one end with black paper to which the specimen is attached, until the specimen is against the bare film. The x-rays then pass through the tube and specimen and register the small image on the film. Subsequently the film is developed, and an enlargement made with a microscope and camera at the magnification desired. The limitation in enlargement is fixed by the grain size of the emulsion used for the radiograph. Ordinarily with Lipmann film the grain becomes more or less objectionable when 300 diameters is exceeded. It is very important that the object examined be in close contact with the emulsion of the film, since the detail recorded is very sensitive to sample-film distance. The x-ray beam employed need not be collimated and the exposures require but a few seconds when the commercial diffraction equipment is employed as radiation source.

Theory

The ordinary absorption laws hold for microradiography and may be expressed as

$$I = I_0 e^{-\frac{\mu}{\rho} \rho x}$$

where μ/ρ is the mass absorption coefficient as listed in the published tables in handbooks, x is the thickness of the sample in centimeters, and ρ is the density of the particular sample used. As may be observed from this expression, the density value ρ and the absorption coefficient fix the absorbing power of the material. The ratio of intensities for x-ray beams passing through two adjacent sections of a given sample (of the same thickness) may be written

$$I_a/I_b = e^{-\left(\frac{\mu_1}{\rho_1} \rho_1 - \frac{\mu_2}{\rho_2} \rho_2\right)x}$$

This expression is approximated below for the two most simple cases: (a) that in which density differentiation is important, the case which may be expected to be most common with biological materials where the absorption coefficient is often essentially identical, and (b) the case in which a variation in chemical composition appears, as for example, in metal alloys, bone or specimens in which some impregnating agent used for "absorption staining":

$$(a) \quad (I_b - I_a)/I_b = (\mu/\rho)x(d_b - d_a)$$

$$(b) \quad (I_b - I_a)/I_b = x(\mu_b - \mu_a)$$

The μ values given in formula (b) are linear absorption coefficients (obtained by multiplying the mass absorption coefficients by the density of the material indicated).

The first formula (a) requires that the sensitivity of the density differentiation on the radiograph be proportional to the differences in density; the second equation (b) that the sensitivity be proportional to the differences in the linear absorption coefficient.

Examples

That certain biological materials would be excellent subjects for microradiographic study is immediately evident. Cellulose, chitin and calcareous structures obviously are suitable because of extreme density variations in the samples or actual variations in chemical content which would correspond to low and high absorption of x-rays.

Figure 1 is a typical microradiograph of a very small insect, in this case a sweat-bee. The spots are identified as pollen caught on very fine hairs. Eyes, antennae, wings, digestional tracts and other anatomical details are readily revealed at magnifications usually of $\times 100$. Microradiographs of wood sections, transverse, longitudinal tangential, and longitudinal radial, are very useful in wood technology. Here especially the addition of the third dimension, as the result of the penetration of x-rays through sections of considerable thickness, adds greatly to the information afforded by the optical microscope.

The high absorbing power of calcium for soft x-rays has been of great importance in ordinary radiography, and so it is to be expected that micrography would be quite successful with bone structures. Such has been the case, especially with extremely small specimens. Replacement of the calcium by other elements, such as lead in lead poisoning, is immediately detected; and as the result of disease variable darkening on the photograph serves to show variable density of the specimen under examination. The suitability of the bone material as subject matter for microradiographic investigations, and the importance of orientation as a function of previous history of the bone suggest that this method may be promising for future investigations in this field.

Other types of biological materials are less suitable for microradiography. Many tissues show good shadows but absence of microscopic structural detail. Moisture and the thickness of the samples used may combine to destroy any detail, since the photograph represents the superposition of effects from a finite thickness. With

such materials it is necessary to use sections thinner than the usual technique would permit for any hope of successful resolution, and longer wave-lengths would certainly be advantageous in the technique. Specimens of the muscle, brain, liver and nerve tissues of a frog and other microtome sections cast acceptable radiographic

FIGURE 1. Microradiograph of body of sweat-bee ($\times 100$), showing density variations of chitin and pollen particles caught on minute hairs.

shadows, but microscopic detail is difficult to observe when monochromatic rays shorter than 1.9 \AA are used from the diffraction tubes usually available.

The method of "absorption staining" or impregnation extends applications of microradiography to many cases where differentiation is difficult. Radiographs were taken of embryonic beans soaked for different lengths of time in lead acetate solution. The progress of the solution into and through the beans was clearly indicated, and stereographic views were taken which enabled the absorption to be viewed in three dimensions. A more suitable demonstration of the possibilities of absorption staining is illustrated by the kidney of a thorotrast-impregnated frog. This microradiograph of a longitudinal section of the kidney shows as the light areas the glomeruli, and indicates that the thorium dioxide could not continue into the lumen of the kidney in the process of excretion, and accumulated at these points.

These are but a few examples of the possibilities of a simple extension of radiography, which though recognized and tried with little success for forty years, has just reached the stage of practical usefulness in a wide variety of biological and industrial fields.

FIGURE 2. Comparison of photomicrographs (right) and microradiographs (left) of some specimens of aluminum-copper alloys used in airplane parts.
(Aluminum dark, copper and alloy phases light.)

Thus far the most important contributions of the science of microradiography have been in the field of metals and alloys. Figure 2 presents comparative photomicrographs and microradiographs of the same areas of three samples of aluminum alloys used in aircraft construction. For the latter the light areas are for the constituents

heavier than aluminum. The control of production of superior airplane motor castings is now being accomplished with microradiographs. Papers by the writer and associates⁵ give many examples of metallurgical applications.

As a more typical colloidal material, Figure 3 shows what may be accomplished with a study of the process of crystallization of inorganic salts, in this case cesium bismuth iodide. The microradiograph shows, at 300 diameters magnification, the very first stages of crystal organization on a skeleton framework, which subsequently fills in. It is evident that here is a valuable addition to the working tools of the colloid chemist, whatever may be his specific interests.

FIGURE 3. Microradiograph ($\times 300$) of first stage in formation of crystals of cesium bismuth iodide.

The Electron Microscope

ALBERT F. PREBUS

Ohio State University, Columbus, Ohio

I. INTRODUCTION

In the endeavor to correlate the observable properties of the substances encountered in all branches of the physical and biological sciences, structural units are sought which are common to a large number of similar materials and the characteristics of which determine with sufficient accuracy the macroscopic properties of the complex substances. The analysis and associated characterization of the significant constituents may be performed with techniques of varying degrees of directness and precision, this depending in a large measure upon the dimensional range in which the structural units are included.

A highly detailed resolution, in the atomic range of dimensions, is provided by a quantitative chemical analysis. This reveals the identity and relative proportions of the chemical elements. Together with certain spectroscopic, x-ray or electron diffraction studies, the existence of recurrent molecular or ionic groups may also be revealed. Interpretation of the data obtained by these means, however, is rapidly beset with difficulties in dealing with structural units which exceed a few millimicrons in size. The existence of such structures may be overlooked entirely if they occur in small numbers or in a random state of aggregation.

In many phases of microbiology, analyses in the atomic range of dimensions provide but meager information. The usefulness of such analyses to research workers engaged in the study of alloys, minerals, textiles, and other high polymers is equally limited. More significant results are obtained by studying the larger molecular aggregates, cells and organisms which can be observed directly with the aid of a microscope. There is, however, a lower limit in the dimensional range amenable to this method of study. It is fixed by the nature of light to between 100 and 200 millimicrons.

Between the upper dimensional limit of atomic analyses and the limit of resolution of the light microscope there exist highly important structural units in both the physical and biological sciences. These include the colloidal particles which bear such labels as crystallites, micelles, fibrils, viruses, and macro-molecules. Reactions in which these units maintain their identity are highly significant. A comprehensive understanding of the physical and chemical properties of these aggregates of sub-microscopic dimensions, of their modes of generation and interaction, and of the mechanisms by which they are bound together to form larger structures, is of the utmost importance in the interpretation of the properties of many substances in the macroscopic form.

The study of matter in the colloidal state of aggregation has been pursued, until very recently, only with the aid of instruments and techniques which provide information of a *statistical character*. The fundamental requirement for the establishment of conclusive data from sedimentation, diffusion, and viscosity experiments and from

observations made with ultra- and polarization microscopes, is the existence in a specimen of large numbers of similar structures. The primary objective of nearly all these experiments is the determination of the physical dimensions of colloidal structures. From these data it is then possible to estimate the magnitude of specific surface properties, which determine in large measure the course of reactions observable on a macroscopic scale.

The electron microscope has been developed with the object of providing a means for the *direct observation of individual structural units* in this dimensional range. Electron micrographs of the colloidal particles occurring in the simpler suspensions or dispersions permit the shape of the particles to be inferred by inspection. Dimensions may be determined with a high degree of accuracy by direct linear measurements in the micrographs. With a practical resolving power below five millimicrons, the presence of isolated particles in the molecular range of dimensions may be detected. The results of shape and size determinations of the simpler colloids with the electron microscope have a more general significance, for they furnish data which permit surface and structure properties to be distinguished. They, therefore, provide an independent means of checking the formulations underlying the indirect methods, which must still be used in the study of many substances which cannot now be investigated successfully with the electron microscope for lack of suitable or reliable techniques of specimen preparation.

Since it is also possible to use the electron microscope within the working domain of the light microscope, an independent means is now available for scrutinizing the conclusions drawn from light microscope observations. This is particularly valuable in the range circumscribing the limit of resolution of the light microscope.

This review is devoted essentially to one of several types of electron optical instruments which are capable of forming magnified images. In the magnetic and electrostatic transmission microscopes, images are produced by means of high-speed electrons (accelerating potentials from 10,000 to 300,000 volts) which have been transmitted through specimens spread in the form of thin films or layers. The mechanism of image formation is in some respects analogous to the manner in which an image of a specimen is formed in the light microscope with either bright-field or dark-field illumination. This similarity, together with the system of lenses, *viz.*, the series *condenser, objective, and projector*, which these instruments have in common with the light microscope, has resulted in the designation of these instruments by the generic term *electron microscope*. Highest resolving power has been attained with magnetic objective lenses. Further development of the electrostatic objective lens undoubtedly will be pursued. A microscope employing the latter type of lens system is inherently more stable and less costly in construction.

Less than ten years have elapsed since the idea of developing an instrument which would surpass the resolving limit of the light microscope was recognized as a practical possibility. The resolving power of present-day instruments has been attained without the necessity of designing corrected lenses. Because of this good fortune, the development has been relatively easy, consisting in the elimination or avoidance of factors which prohibited the attainment of the highest resolving power of which the simple uncorrected lenses were capable. As a consequence, investigations of an intensive character are few. A thorough and comprehensive evaluation of the characteristics and limitations of the instrument cannot be carried out. Nevertheless, an extensive review of the fundamental concepts of the instrument, rather than of instrument accomplishments, was considered to be more valuable. Current reviews of this character do not exist in the English language. Several books, written in Germany, are difficult to obtain at the present time.

It has frequently been stated by electron-microscope workers that the interpretation of the electron microscope image is a matter of great simplicity in comparison with that of the light-microscope image. Such a comparison is not justified without

qualifying statements to specify the observable image data which is selected for consideration. Further, the relative ease of making conclusive observations from microscope images depends upon the dimensions of the observed structures relative to the resolving limits of the respective instruments. The research worker using the microscope as a tool in a specific investigation is in both cases confronted with the problem of interpreting the nature of his material in terms of the characteristics of the specimen observed in the microscope. The writer has endeavored to indicate the complexities of the problems involved in relating the photographic density variations in a micrograph with the phenomena of electron scattering in the specimen material. The most instructive theoretical and experimental contributions of many investigators have been taken into consideration. They provide, even to the most enthusiastic advocate of the electron microscope, only data of a qualitative character. Only the most elementary data provided in the electron microscope image can be utilized with reasonable assurance of accurate interpretation. The criticisms and suggestions of the writer have been made with the object of pointing out some of the pitfalls which may be encountered and of indicating the directions in which further intensive experimental work is urgently required. It is the nature of scientists to exploit their tools to the limits of their usefulness. In the range about the limit of resolution of present-day electron microscopes, the interpretation of the images is intimately related to the aberrations of electron lenses. This provides an additional reason for devoting considerable space to electron lenses in this paper.

II. ELECTRON LENSES

The science of electron optics is an outgrowth of the fundamental discovery in 1926 by Busch⁵² that the magnetic field in the neighborhood of the axis of symmetry of a circular solenoid possesses the properties of a lens with respect to radiation consisting of electrons or ions. Shortly thereafter, the lens characteristics of certain axially symmetrical electrostatic fields was recognized by Davisson and Calbick⁵⁵ and by Brüche and Johannson.⁴⁹ The early rapid development of magnetic electron lenses into useful electron optical instruments is due almost entirely to Ruska and associates,^{95, 96, 97} then in the Technische Hochschule, Berlin. Intensive study of the electrostatic electron lenses, more versatile in technical applications, was taken up initially by Brüche and associates in the AEG Laboratories. In this same period, 1931 to 1936, the main theoretical aspects of electron optics were clarified, notably by Glaser and Scherzer. Descriptions and numerous references to this phase of the development and applications of electron lenses are included in the books of Busch and Brüche,⁵³ Myers,¹²⁵ Klemperer,⁹⁴ and Zworykin and Morton.¹⁶³ Further discussion here is limited to the main features of those lenses which have found application in electron transmission microscopes.

FIGURE 1a. Simple magnetic electron lens.

The Cardinal Points of Strong Magnetic Lenses. A simple magnetic electron lens is illustrated in Fig. 1 (a). CC' represents the cross-section of a solenoid through the axis of symmetry AA' . The incompleted arcs illustrate the configuration of the lines of force of the magnetic field. If an object in a plane perpendicular to the axis AA' and intersecting it in O , distant a from the center of the coil, emits or scatters electrons of uniform speed in a beam of small aperture α , an image is formed in the plane perpendicular to the axis and intersecting it in I , distant b from the coil center.

In the first approximation, the differential equations governing the trajectories of the electrons on their passage through the magnetic field may be reduced to the form⁵²

$$\left. \begin{aligned} \frac{d^2 r}{dz^2} + \frac{e}{8mc^2 U} \cdot H^2(z) \cdot r &= 0 \dots\dots (a) \\ \frac{d\theta}{dz} &= \sqrt{\frac{e}{8mc^2 U}} \cdot H(z) \dots\dots (b) \end{aligned} \right\} \quad (1)$$

where z is the distance along the axis AA' with arbitrary origin; r is the radial distance of the electron from the symmetry axis; θ is the angular displacement of the trajectory in the cylindrical coördinate system r, θ, z ; $H(z)$ is the magnitude (emu) of the z -component of the magnetic field on the axis of symmetry; U is the accelerating potential (esu) of the electron beam; and e, m, c , have their customary significance.

Reduction of equation (1a) from the general Lorentz equation by Busch represents the discovery of the magnetic electron lens, for linearity of this equation in r implies that any axially symmetrical field free of current sources in the neighborhood of the axis may be regarded as a convergent symmetrical lens for electron beams of small aperture and homogeneous velocities. If the electron trajectory is considered to be confined in a plane containing the axis of symmetry, equation (1b) signifies that the plane of the trajectory rotates, the amount of rotation between any two axial points z_a and z_b being given by the integration of equation (1b) between these limits, *vis.*,

$$|\theta| = \sqrt{\frac{e}{8mc^2 U}} \cdot \int_{z_a}^{z_b} H(z) dz \quad (2)$$

The magnetic lens does not in general provide an erect or inverted image. The image plane is rotated about the optic axis relative to the object plane through an angle determined by equation (2) with the limits of integration extended from the object to the image planes.

Under conditions in which the electron trajectories entering the field parallel to the optic axis are converged to a focal point at a large distance from the coil center, relative to the axial extent of the field, the lens is considered as thin and weak. Equation (1) may be integrated with sufficient accuracy by making the approximation that r remains sensibly constant within the field. In this case the focal length of the lens is determined by the relation

$$1/f = \frac{e}{8mc^2 U} \int_{-\infty}^{+\infty} H^2(z) dz \quad (3)$$

This formula becomes increasingly inaccurate as the focal point approaches the region in which the field is appreciable and fails entirely to describe the optical properties of the lenses used in a transmission electron microscope.

The shortest focal length attainable with a simple coil is determined by the mean diameter D_c . For electrons with speeds in excess of 10,000 volts, required in a

transmission microscope, coils of large dimensions are required to converge the electrons, and focal lengths below several centimeters are not experimentally attainable. This limitation in the attainment of high-power lenses for fast electrons was removed by the introduction of the iron-encased solenoid by Knoll and Ruska in 1931.⁹⁵ By this means the magnetic field of a coil of arbitrary cross-section may be effectively concentrated into a small volume without destruction of image-forming properties. The diameter of the equivalent simple coil is determined by the internal radius of the terminals, or *pole pieces*, of the iron case between which the field is concentrated.^{16, 134} Such a coil, in which the internal diameter of the pole pieces is denoted by D_p , is illustrated in Fig. 1 (b).

FIGURE 1b. Iron-encased short focal length magnetic electron lens. In the limiting case of thin and weak lenses, $1/a + 1/b = 1/f$ and $1/f = c \int_{-\infty}^{\infty} H^2(z) dz / 8mc^2 U$.

Empirical corrections have been applied¹³⁴ to the formula (3) to represent the focal lengths of the short focal length lenses obtained with the iron-encased solenoids. Even these, however, have been found inadequate to describe quantitatively the optical properties of strong lenses.

Although the formal optical theory of electron lenses has been developed to a satisfactory degree,^{65, 144} general methods for the computation of the optical constants of strong magnetic lenses in terms of the geometrical and magnetic constants of the pole pieces have not yet been developed. Neither is it possible to determine the optical properties by exact analytical methods in terms of arbitrary theoretical or experimental magnetic fields. The construction of pole piece units to provide lenses with specified cardinal points and with certain aberrations reduced to minima, consequently has not yet been attempted.

The most comprehensive descriptions of the optical properties of the types of magnetic lenses used in transmission microscopes have been provided by Glaser⁶⁶ and Dosse.^{56, 57} In the publication of Glaser, an analytic function is selected which represents with reasonable accuracy the field in a strong lens and which permits differential equation (1a) to be solved exactly. This procedure leads to a clear picture of the dependence of the cardinal points and of the important aberrations on the strength and width of the lenses.

With the function

$$H(z) = H_0 / \left(1 + \frac{z^2}{a^2} \right) \quad (z = 0 \text{ where } H(z) = H_0) \quad (4)$$

representing the magnetic field on the axis of symmetry, the "strength" of the lens is described by the parameter

$$k^2 = \frac{eH_0^2 d^2}{8mc^2 U} \quad (5)$$

and the "half-width" by the parameter d , equal to the axial distance from the maximum of the field to the point at which it has one-half of this value. In the case of the function (4), the half width d is equal to a .

By exact solution of equation (1), the focal points z_{f_0} , z_{f_1} of the lens can be expressed analytically by the simple relations

$$\left. \begin{aligned} z_{f_0} &= a \cot \frac{\pi}{\sqrt{1+k^2}} \dots\dots (a) \\ z_{f_1} &= -a \cot \frac{\pi}{\sqrt{1+k^2}} \dots\dots (b) \end{aligned} \right\} \quad (6)$$

and the corresponding focal lengths f_0 , f_1 by the relations

$$\frac{1}{f_0} = -\frac{1}{f_1} = \frac{1}{a} \sin \frac{\pi}{\sqrt{1+k^2}} \quad (7)$$

The positions of the principal points h_0 , h_1 are determined by the relations

$$\left. \begin{aligned} z_{h_0} &= a \cot \frac{\pi}{2\sqrt{1+k^2}} \dots\dots (a) \\ z_{h_1} &= -a \cot \frac{\pi}{2\sqrt{1+k^2}} \dots\dots (b) \end{aligned} \right\} \quad (8)$$

From inspection of equation (7), it may be concluded that the shortest attainable focal length is equal to a , the half-width of the symmetrical field (4). This obtains when $k^2 = 3$. If k^2 is greater than 3, there are more than one pair of focal points in the lens, and multiple images occur. The impaired image definition resulting from multiple images has made it customary to avoid this range in electron microscope lenses. The following discussion is therefore restricted to the range of k^2 below the value 3.

If Z_o , Z_i , represent conjugated object and image distances measured from the focal points, *viz.*, $Z_o = z_o - z_{f_0}$, $Z_i = z_i - z_{f_1}$, they may be related by Newton's lens formula

$$Z_o Z_i = f_0 f_1 \quad (9)$$

The above analysis has demonstrated that the determination of conjugated object and image elements by the familiar Listing construction, based on a knowledge of only the cardinal points, is applicable in the case of strong magnetic lenses even with the object and image positions within the field. The positions of the cardinal points in a lens of this type, in terms of the parameter k^2 , are illustrated in Fig. 2 (Fig. 6A⁶⁶).

A comparison of these theoretical values with experimental measurements by Dosse⁵⁷ indicates that the function (4) is an inadequate representation of the magnetic fields in the range most frequently used in an objective lens. The measured fields are more sharply defined and become extended to fit equation (4) only when the saturation point in the material of the pole pieces is exceeded. In the useful range of field intensities, the fields have not been amenable to description with sufficient accuracy by any known function which makes equation (1) exactly soluble.

FIGURE 2. Principal points H_0 , H_1 and focal points F_0 , F_1 as functions of the parameter k^2 of strong magnetic lenses having the axial field distribution $H(z) = H_0/(1 + z^2/a^2)$. The focal lengths are given by the relations: $f_0 = z_{H_0} - z_{f_0}$; $f_1 = z_{H_1} - z_{f_1}$.⁶⁶

Dosse,⁵⁷ therefore, carried out the calculation of the cardinal points for normal field distributions by numerical methods. In this investigation, the measured fields are described by the function

$$\xi_3 = \frac{H(z)}{H_0} = e^{-\frac{z^2}{a_3^2}}, \quad a_3 = 1.20d \quad (10)$$

the limiting case of the function

$$\frac{H(z)}{H_0} = \frac{1}{\left(1 + \frac{z^2}{a_3^2}\right)^\mu} \quad \text{as } \mu \rightarrow \infty \quad (11)$$

The accuracy with which the analytic fields (4) and (10) represent the measured fields in the two ranges (below and above saturation in the pole pieces) is illustrated in Fig. 3 (Fig. 1⁵⁷). In this chart, curve 1, representing equation (4), follows closely the measured field, curve 5, obtained beyond the saturation point. The limiting function (10), shown as curve 3, is a better approximation to the normal field, shown as curve 4.

In consequence of the variable permeability of the pole-piece material, it is evident that the shape of the $H(z)$ curve makes a gradual transition from the forms 4 to 5 as the current (ampere-turns) in the solenoid of the lens is increased. The comparison of the dependence of the focal length on k^2 in the two limits is therefore of interest. This is shown in Fig. 4 (Fig. 5⁵⁷), in which curve 1 demonstrates equation (7); curve 2 the numerically computed values on the basis of equation (10); and curve 3 the focal lengths in the ideal field $H(z) = H_0$ in the interval $-d$ to $+d$. For a given beam potential U and fixed pole-piece dimensions, the focal length decreases with increasing H_0 (determined by the current in the coil). In the range of small k^2 , or large focal lengths, the variation may be expected to follow the trend of curve 2. As saturation is approached, the width of the field increases, and the focal length

decreases with increasing k^2 in a manner as yet undescribed until saturation is established. From this point onward, the focal length varies with k^2 in accordance with curve 1. The numerical range of k^2 in which this transition takes place depends upon

FIGURE 3. Theoretical and experimental axial fields, $H(z)$, of strong magnetic electron lenses. Curve 1: theoretical field $H(z) = H_0/(1 + z^2/a^2)$; curve 2: theoretical field of a simple coil with one turn of radius a_2 ; curve 3: theoretical field $H(z) = H_0 \exp(-z^2/a_3^2)$; curve 4: measured field in the normal case of unsaturated pole pieces; curve 5: measured field in the case of saturated pole pieces.⁵⁷

U , decreasing with increasing U . A complete description of a magnetic lens (in terms of the general function (11)) would require the field to be expressed in the form of (11) with μ as a function of k^2 , defined uniquely for fixed values of U .

An experimental comparison is illustrated in Fig. 5 (Fig. 8⁵⁷). Although a numerical correlation of k^2 with the ampere turns (NI) in the coil and data of the pole pieces is lacking, it may be estimated by a comparison of these results with the earlier measurements of Ruska.¹³⁴ It is nevertheless interesting to observe the excellent agreement between the calculated value of the focal length, curve 5, on the basis of equation (10), with the experimental curves 1, 2, 3, 4, for small k^2 . The agreement between the calculated values (marked x) on the basis of equation (4) with the focal lengths in the saturation range, further verifies the accuracy of these theoretical methods. In the electron microscope, the lenses are generally used in the range of k^2 preceding the establishment of complete saturation, with focal lengths somewhat above the minimum values.

(b) **Spherical and Chromatic Aberrations of Strong Magnetic Lenses.** The second approximation in the derivation of the lens equation from the general Lorentz equation reveals the existence and character of the third-order lens aberrations. These have been classified and labelled^{65, 144} in terms of the known third-order aberrations

FIGURE 4. The focal length f (f_0 or f_1) of a magnetic lens as a function of the parameter k^2 . Curve 1: with the field $H(z) = H_0/(1 + z^2/a^2)$; curve 2: with the more sharply defined field $H(z) = H_0 \exp(-z^2/a^2)$; curve 3: with the ideal most sharply defined field $H(z) = H_0$ ($-d < z < d$), $H(z) = 0$ ($z < -d$, $z > +d$).⁵⁷

FIGURE 5. Experimental determination of the focal length f of a strong magnetic lens as a function of k^2 . Points 1, 2, 3, 4: calculated focal lengths for the case of saturated pole pieces.⁵⁷ curve 5: calculated focal lengths for the normal case of unsaturated pole pieces.

of light lenses. Of particular interest in the study of microscope objective lenses is *spherical aberration*, the only aberration not reduced to zero as the object point approaches the optic axis of the lens. As a result of this aberration, the image of an axial object point appears as a disc of illumination, the radius of which, Δr , is proportional to the cube of the aperture α of the lens (see Fig. 1). This radius, divided by the image magnification, is used as a measure of the spherical aberration, denoted by the symbol δ_s . If V is the magnification, then

$$\delta_s = \frac{\Delta r}{V} = C_s \cdot \alpha^3 \quad (12a)$$

where C_s is a constant of the lens for fixed object and image positions.

In the case of the field represented by equation (4),

$$C_s/a = \left[\frac{\pi k^2}{4(1+k^2)^{3/2}} - \frac{1}{8} \frac{4k^2-3}{4k^2+3} \cdot \sin \frac{2\pi}{\sqrt{1+k^2}} \right] \frac{1}{\sin \frac{4\pi}{\sqrt{1+k^2}}} \quad (12b)$$

The analytical expression, equation (12b), for the case in which the object is at a focal point is shown by the dotted curve marked γ_s in Fig. 6.⁵⁷ It has been shown by Glaser that the minimum spherical aberration, insofar as it depends upon a selected object position, differs inappreciably from the values shown in the figure. The effect on the spherical aberration constant C_s of a dissymmetry in the field has been computed by Dosse.⁵⁶ In the practical range of k^2 , the aberration increases rapidly to large values if the half width on the object side of the lens is less than the half width on the image side. The aberration is reduced in a comparatively small proportion if the larger

FIGURE 6. Spherical C_s and chromatic C_F aberration constants of magnetic lenses as a function of k^2 . Curve γ_s (full) — calculated ratio C_s/d for unsaturated pole pieces; curve γ_s (dotted) — calculated ratio C_s/d for saturated pole pieces; curve γ_F (full) — calculated ratio C_F/d for unsaturated pole pieces; curve γ_F (dotted) — calculated ratio C_F/d for saturated pole pieces.⁵⁷

half width is on the object side. Some advantage, therefore, is gained by constructing the pole pieces with a larger internal diameter on the object side of the lens.

The numerically computed spherical aberration constants for the normal unsaturated fields, shown as the full γ_s curve in Fig. 6, agree very closely with the values which may be inferred from the analytical expression, equation (12b). For the purpose of estimating the effect of this aberration on the resolving limit of magnetic lenses [see Sec. III(c)], the analytical expression consequently appears to be adequate. The failure of this analytical method for the calculation of the cardinal points of strong microscope lenses, however, is well illustrated in Fig. 5.

The experimental measurement of the spherical aberration of objective lenses is difficult to carry out with high accuracy. The method of von Ardenne¹¹ requires the use of excessively large apertures to enhance the aberration to a sufficient extent to make it measurable. The experimental observations must subsequently be extrapolated several orders of magnitude to the range of lens apertures used in practice. A similar criticism applies to the method of von Borries and Ruska,⁴⁴ in which the spherical aberration is thought to be isolated by use of large lens apertures in a normal microscope image. The extrapolation is not justified because of the existence of errors of higher order. In the method of von Borries and Ruska, it is further doubtful if the assumed apertures obtain experimentally. Probably the most accurate measurements are those of Dosse,⁵⁷ using the method suggested by Boersch.³⁸ These experimental results agree very well with the theory reviewed above, thereby showing that the results of Ruska and von Ardenne are several orders of magnitude too high.

As the focal length of a magnetic lens is determined by the parameter k^2 , containing the ratio H_0^2/U , it varies with independent variations of either H_0 or U . Independent variations of H_0 can be eliminated experimentally, for the field is determined by the current in the coil of the lens. It is therefore sufficient in this discussion to consider only the effect of variations in U . In consequence of a variation ΔU in the accelerating potential of the electron beam, the image of an axial object point appears in the original image plane as a disc of illumination. The radius of this disc, when divided by the magnification, is a measure of the chromatic aberration of the lens. It may be expressed in the form⁶⁶

$$\delta_F = C_F \frac{\Delta U}{U} a \quad (13)$$

where C_F is termed the chromatic aberration constant of the lens.

An analytical expression for C_F can be derived if the equation (1) is exactly soluble. On the basis of the theoretical field (4), Glaser obtained the expression

$$C_F/a = \frac{\pi k^2}{2(1+k^2)^{\frac{1}{2}}} \cdot \frac{1}{\sin^2 \frac{\pi}{\sqrt{1+k^2}}} \quad (14)$$

The chromatic aberration constant in this case is illustrated as a function of k^2 by the dotted curve marked γ_F in Fig. 6. Numerically calculated values, on the basis of the field (10), are illustrated by the full curve γ_F . The agreement in the range of small values of k^2 indicates that the chromatic aberration of magnetic lenses can be estimated with adequate accuracy by use of the analytical expression, equation (14).

With the exception of the test measurements of Dosse,⁵⁷ direct experimental measurements of the chromatic aberration of strong magnetic lenses have not been reported. The example given by Dosse demonstrates the agreement between the theoretical calculations and experimental measurements. For the case $U = 78 \text{ kV}$, $\Delta U = 360 \text{ volts}$, $f = 2.4 \text{ mm}$, the measured value of the chromatic aberration leads to

a value of C_F between 1.35 and 1.65 mm. The corresponding theoretical value, deduced from Fig. 6 ($d = 1.7$ mm, $NI = 3900$, $k^2 = 0.64$) is 2.0 mm.

(c) **The Electrostatic Objective Lens.** The electrostatic electron lenses are more closely related to ordinary optical systems. Any axially symmetric electrostatic field, which, together with its derivatives, is continuous in the neighborhood of the axis of symmetry, may be regarded as an electron lens. The square root of the potential at any point is equivalent to the refractive index and the entire field to an inhomogeneous isotropic optical medium. In an axially symmetrical field the curvature of the equipotential surfaces is spherical in the neighborhood of the axis, and so the field may be regarded as a lens system composed of an infinite number of adjacent and centered spherical refracting surfaces. The differential equation governing the trajectory of a paraxial electron traversing an electrostatic field of this character may be written in the form¹⁴⁵

$$V(z) \frac{d^2 r}{dz^2} + \frac{1}{2} \cdot \frac{dV}{dz} \cdot \frac{dr}{dz} + \frac{1}{4} \cdot \frac{d^2 V}{dz^2} \cdot r = 0 \quad (15)$$

where $V(z)$ is the electrostatic potential on the axis of symmetry and r is the radial displacement of the electron from the z axis. The image-forming properties of such a field are contained in the observation that the equation is linear and of the second

FIGURE 7. Electrostatic unipotential electron lens. The outer electrodes E E' are at a potential U , equal to the accelerating potential of the illuminating electron beam. The potential V_f of the focusing electrode determines the focal length f of the lens. In the limiting case of a thin and weak lens $1/a + 1/b = 1/f$; $1/f =$

$$\int_{-\infty}^{\infty} \left[\left(\frac{dV}{dz} \right)^2 / V^{\frac{3}{2}} \right] dz / 8U^{\frac{1}{2}}$$

order in r . Axial potential distributions with the necessary symmetry and continuity characteristics can be produced by applying potentials to a system of annular electrodes possessing rotational symmetry about a common axis. These electrodes may consist of any combination of cylinders, discs or cones.

Electrostatic lenses have been divided into two classes. In the *bipotential*, *immersion* or *accelerating* lenses, there is a potential difference between the object and image spaces. In the *unipotential* or *Einzellens*, the potentials in the object and image spaces are equal. The bipotential lenses are particularly useful in the study of electron-emitting surfaces and in cathode-ray tubes in which it is desirable to combine the functions of accelerating the electrons and producing images in a single electrode system. The unipotential lens has been found more suitable for use in transmission electron microscopes.

This type of lens is illustrated in Fig. 7.⁸⁸ The outer electrodes EE' have potentials applied to them equal to the accelerating potential, U , of the illuminating beam.

The potential V_F of the inner or *focusing* electrode may be either positive or negative relative to the outer electrodes. In a transmission microscope objective lens it is convenient to select a focusing potential which lies between the cathode-anode potential of the electron beam. The value depends upon the dimensions of the electrodes and the desired focal length. The specimen is situated very close to the first outer electrode at O , and the image is formed at a considerably greater distance from the lens at I . In order to attain the short focal lengths which are required in a transmission microscope, the internal diameters of the electrodes and the spacing between them cannot exceed a few millimeters. An aperture-limiting diaphragm with internal diameter below $\frac{1}{10}$ millimeter is also desirable to enhance the contrast in the image and to reduce the spherical and chromatic aberrations of the lens. Since introduction of a diaphragm of arbitrary form would seriously distort the electrostatic field and its image-forming properties, it is necessary to provide an aperture diaphragm which is formed to replace a natural equipotential surface. The adopted procedure consists in forming one of the three lens electrodes with a sufficiently small internal diameter. In the instruments described by Mahl¹⁰⁵ and by Bachman and Ramo,²⁶ the outer electrode on the image side of the lens serves as an aperture. The diameter and shape of the focusing electrode is made so that a lens of selected focal length is obtained when this electrode is at cathode potential. This procedure obviates the necessity for a voltage divider in the high-voltage circuit and results in a lens of fixed focal length entirely independent of the accelerating potential of the electron beam. With the focusing electrode serving as an aperture diaphragm, a natural equipotential surface of a predetermined field distribution can be duplicated more precisely in principle. However, mechanical errors in forming the electrode are considerably more serious and a voltage divider is required.

In view of the fact that the electrode surfaces of the lenses are equipotentials, it is in principle an easy problem to compute the dimensions and positions of the electrodes which will produce a desired axial potential distribution. One procedure, demonstrated by Plass¹²⁰, consists in expanding the series solution of the Laplace equation,⁵⁰ *viz.*,

$$V(z,r) = \sum_{\nu=0}^{\infty} \frac{(-)^{\nu}}{(\nu!)^2} \cdot V(z)^{(2\nu)} \cdot \left(\frac{r}{2}\right)^{2\nu} \quad (16)$$

in terms of the axial function $V(z)$ to obtain the equipotential surfaces corresponding to each point on the axis. Electrodes shaped to conform to a small number of these equipotentials in regions removed from the axis may then be charged to the correct potential to provide the selected axial potential distribution. Electrode configurations for a few special axial functions may be computed by exact methods. Some of these are reviewed by Bachman and Ramo.^{26a}

Although there are many methods available for the determination of the axial potential distributions of given electrode configurations, and subsequently the electron trajectories and aberrations,^{34, 26a, 129, 163} relatively little data concerning the strong unipotential lens have been published.

Theoretical estimates of the magnitudes of the aberration constants of this type of objective lens have been reported by Dosse⁵⁷ and by Bachman and Ramo.^{26a} In both investigations, numerical computations were carried out for special axial potential distributions which describe approximately the fields of real, strong lenses. The computations of Dosse indicate that the magnitudes of the spherical and chromatic aberration constants are from 5 to 10 times greater than in the equivalent magnetic lens.

The value of the spherical aberration constant estimated by Bachman and Ramo is somewhat smaller. In both investigations it is recognized that the chromatic aberration constant is greater in the electrostatic lens than in the magnetic lens. The latter result is not apparent if the lenses are considered as thin and weak.

The dependence of the focal lengths of both types of electron microscope lenses on the velocity distribution in the illuminating beam results in a reduction of the image definition in those areas of a specimen which are effective in destroying the velocity homogeneity of the illuminating beam. In the case of the magnetic lens, chromatic aberration may result from two additional sources which are independent of electron scattering in the specimen. These are variations in the accelerating potential of the illuminating beam and in the current of the lens.³ An additional source of chromatic aberration in the electrostatic lens may also arise if the focusing potential is not maintained as a constant fraction of the cathode-anode potential of the illuminating beam. Departure from constancy may occur in a lens in which the focusing potential lies between the cathode-anode potential. Circuit reactances in the voltage divider must be adjusted to maintain a constant phase between the anode and focusing potentials relative to the cathode with an unregulated voltage supply if the effect is to be avoided.

The effect of the above aberrations on the resolving power exhibited in normal electron microscope images cannot be predicted quantitatively in terms of the above simple formulas. For a real specimen, an integration in the image plane must be performed in which both the distribution of the velocities of the scattered electrons and their angular distribution within the angle α are known. At the present time, only the qualitative data provided by the early scattering experiments are available. These data and the calculation of the magnitude of the chromatic aberration for various specimen thicknesses and beam voltages are presented in graphical form in publications of von Ardenne.^{3, 5, 7}

(d) **Diffraction Aberration.** Although the effects of spherical and chromatic aberrations on the resolving power of a lens may be reduced without limit by reduction of the beam aperture α , there is a limit beyond which a third aberration becomes evident. This aberration is the electron-optical equivalent of *diffraction*, the limiting factor on the resolving power of the light microscope. It has been assumed that the kinematic wave theory of diffraction and the Abbe theory of microscope vision may be extended to describe the effects of diffraction on the resolving power of the electron microscope. It is of interest, therefore, to examine the conditions under which the validity of the extension might be verified experimentally. In the first case, an object is required in the form of an idealized line transmission grating of many elements. A beam of parallel light of wave-length λ incident on such a grating at an angle θ_K to its normal, but perpendicular to its elements, is scattered coherently. Sharply defined interference maxima occur at angles of inclination, θ , to the normal in accordance with the relation $n\lambda = \delta_a (\sin \theta_K + \sin \theta)$, where $n = 1, 2, 3, \dots$ and δ_a is the grating interval. If the aperture of the objective lens is sufficiently large to receive both the zero order and the first order maxima which has the lesser inclination to the normal of the grating, the illumination in the image plane of the lens consists of a series of maxima and minima of intensity. The period of this pattern, when divided by the magnification, is equal to the period of the grating. The total number of diffraction maxima traversing the lens determines the degree of similarity of the image with the object. If not more than one order of the pattern enters the lens, the illumination in the image plane appears uniform and resolution of the grating is not obtained. Therefore, with oblique illumination and an objective lens of angular aperture α , the smallest grating space δ_a which can be resolved in the absence of other aberrations is determined by the relation $\delta_a = \lambda / (\sin \theta_K + \sin \alpha)$. If the specimen is mounted in a medium of refractive index μ , the objective lens aperture is circular,

and the illuminating beam is symmetrical about the optic axis with an aperture α , the above relation is modified to the form

$$\delta_d = \frac{1.22\lambda}{\mu(\sin \theta_R + \sin \alpha)} \quad (17)$$

This limiting formula therefore applies in the study of periodic structures of many elements and the resolution is determined essentially by the Fraunhofer diffraction arising in the object.

An alternative formula is applicable if the specimen consists of only two incoherent scattering centers or of two idealized independent point sources of illumination in the plane of the specimen. In this simple case, the illumination observed in the image plane consists of a pair of incoherent diffraction patterns resulting from Fresnel diffraction at the lens diaphragm. Under conditions which these two patterns may be just distinguished, the points are said to be resolved. The minimum distance of separation of the points in the object plane when they are resolved in accordance with the Rayleigh criterion is given by the formula

$$\delta_d = \frac{\lambda}{2 \mu \sin \alpha} \quad (18)$$

This formula, directly applicable to an electron lens, has also been deduced from the uncertainty principle by Henriot. It is derived in a publication of Marton, Banca and Bender.¹¹⁵

Although von Ardenne³ and von Borries and Ruska^{42, 44} have adopted formula (17) and its implications to represent the limiting effects of diffraction on the resolving power of the electron microscope, the reasons for this choice are not apparent. Isolation of the diffraction aberration resulting from diffraction in the object plane would require a specimen consisting of a one- or two-dimensional grating with a period above the optimum resolving power of present-day objective lenses, at least 50 Å. With a modified criterion for resolution which takes into account atomic scattering amplitudes, the kinematic treatment is apparently justified.

It appears more logical to attempt the isolation of the diffraction aberration under conditions in which formula (18) is applicable. A suitable point source of illumination in the object plane might consist, for example, of a small opening (below 50 Å in diameter) in a heavy metallic foil illuminated by a beam of aperture equal to or greater than the aperture of the objective lens as determined by a metallic diaphragm. By this method, it is in principle possible to determine the distribution of the illumination within the objective aperture. Isolation of the Fresnel diffraction pattern originating in the lens diaphragm should be possible by reducing the aperture of the objective lens well below the value permitting attainment of optimum resolution. Validity of the extension of the kinematic wave theory to this case appears justified in view of the character of the straight-edge Fresnel diffraction pattern observed by Boersch.³⁹

III. THE TRANSMISSION ELECTRON MICROSCOPE IMAGE

(a) **Physical Interpretation of Micrograph Observables.** The mechanism of image formation in the transmission electron microscope is illustrated in Fig. 8. A simple specimen consisting of a small massive particle M supported on a thin film, is mounted immediately above the principal focus of the objective lens, in this illustration a magnetic lens, the pole pieces of which are denoted by N , S . The part B of the illuminating beam incident on the particle is scattered by it from a well-defined pencil of aperture δ (10^{-4} to 10^{-2} radian) into a diffused beam, the aperture of which is represented by α_0 . The metal diaphragm D , in the magnetic field between the pole pieces, permits the passage of only a fraction of these scattered electrons through the

lens, *viz.*, those contained within the cone of aperture α . An illuminating pencil A , incident on an opening in the supporting film, is not scattered. With the aperture δ smaller than α , the entire incident pencil is transmitted through the lens. When the final image, formed by the pencils A' , B' , is observed on the fluorescent screen, the image of the opening appears bright, and the image of the particle dark.

FIGURE 8. A convergent electron beam A incident upon an area free of material passes unscattered through the aperture diaphragm D between the pole pieces N , S of the objective lens. The image of such a clear area appears bright. An adjacent beam B striking a particle M in the specimen is scattered into a divergent beam. Only a fraction of the scattered electrons pass through the aperture of the lens to reach the image plane. The image of such a particle, therefore, appears dark. In the absence of a limiting diaphragm D , the image contrast is governed by the spherical aberration constant of the lens.

Well-defined images and adequate image contrast for the study of many materials may also be obtained without the use of an aperture-limiting diaphragm. This is thought to be primarily a consequence of the large spherical aberration constants of present-day electron lenses. The electron beam incident on an opening H (see Fig. 8) suffers no angular scattering and therefore passes through the objective lens with an aperture δ equal to that of the illuminating system. The boundary of such an opening is defined with high resolution by the electrons transmitted through the opening. An appreciable fraction of the electrons incident on any point in the supporting membrane are scattered over relatively large angles (of order 10^{-2} radian). Some of these appear in a diffraction pattern as diffuse rings, and as a consequence of spherical aberration, reach the image plane in areas far removed from the conjugated image points. A proportion of the electrons transmitted through the film thus arrives in the image plane within the area occupied by the Gaussian image of the opening. The total intensity within the latter area is the sum of the intensity transmitted through the opening and the scattered radiation from neighboring material. Only a small fraction of the electrons transmitted through a particle M in the specimen arrive in the image plane within the area representing its image. The remainder are scattered over the entire field of view, thereby enhancing the background intensity.

On the basis of the above qualitative explanation, it is apparent that the effective width of the intensity transitions in crossing the boundary between mass or thickness discontinuities is determined by the resultant of the aberrations in the area causing the *lesser* angular scattering. Although the resolving power within areas representing massive particles may be exceedingly low, the peripheries of such particles may

be sharply defined if the particles are suspended freely, or supported on a film of small density and thickness. In view of the fact that the peripheries of particles are defined with nearly equal sharpness either when they are supported freely or on a thin supporting film, it must be concluded that the effective angular aperture of the electrons scattered by such thin films is of the order of 1×10^{-3} radian. The electrons scattered over wide angles, such as those scattered coherently, have little effect upon image definition, but are responsible for the image contrast.

In general, both image contrast and definition are improved by use of an aperture-limiting diaphragm in the objective lens. An obvious exception occurs in the observation of the peripheries of particles suspended in the specimen without a supporting membrane. In the latter case, the definition is determined by the aperture of the illuminating beam alone.

The mechanism of image formation discussed above results in an interesting contrast between light and electron microscope images. Whereas the resolving power exhibited in a photomicrograph is essentially constant over the entire field of view, there are large variations in the resolving power over the field of view of an electron micrograph. In the bright background and about the peripheries of well-defined structures supported freely or by a thin supporting membrane, the optimum resolving power may always be attained. In the interior of a massive structure the resolving power is reduced, and with structure thicknesses above *ca.* 50 millimicrons, may be comparable with or less than the resolving power in a photomicrograph. This observation is of importance since it indicates that large structures commonly studied in the light microscope may also be studied with advantage in the electron microscope. Significant boundary details, obscured in a photomicrograph, are frequently revealed in an electron micrograph.

The immediate data provided by the image are two-fold. Providing there is sufficient image contrast, the *cross-section dimensions* of a structure obstructing the continuous rectilinear propagation of the electrons are immediately apparent. The *intensity differences* in the images of neighboring structures contain further information regarding the third dimensions of the structures and their composition.

The two dimensional image of a structure is not the image of a cross-section through any well defined plane, since the focal depth of the electron microscope is very large. With a resolving power δ_R , focal length f , and lens aperture diameter D , the focal depth is given by the relation

$$T = \frac{2 \cdot f \cdot \delta_R}{D} \quad (19)$$

In accordance with this simple formula, a focal depth of two microns is obtained with a resolving power of 3 millimicrons and a lens aperture $\alpha = 1.5 \times 10^{-3}$ radian.

The above formula may be regarded as reasonably accurate only if the objective lens aperture is defined by a mechanical diaphragm and is equal to or less than the aperture of the illuminating beam. In the absence of a mechanical diaphragm, the focal depth is a function of the angular scattering produced by the adjacent object elements used as test objects. It is determined essentially by the effective aperture of the scattered electrons emanating from the specimen area causing the lesser scattering. In the case of freely suspended specimen material, the focal depth, therefore, may be estimated by replacing $D/2f$ in formula (19) with the aperture of the illuminating beam. In consequence of this large focal depth, it is possible to change the inclination of the specimen relative to the optic axis and by superposition of the resulting micrographs to infer the magnitude of the third dimension (within the limits discussed in Section VI). Descriptions of several methods for obtaining stereoscopic micrographs and numerous illustrations are included in the publications of von Ardenne,¹⁸ Mahl¹⁰⁴ and others.

Interpretation of the relative *intensities* in the electron microscope image is a much more complex and difficult problem. At the present time even qualitative conclusions regarding the significance of relative image intensities are not always beyond question. The earliest experiments performed with cathode rays by Lenard¹⁰¹ and others were concerned with the establishment of empirical laws governing the changes in intensity, the average change in speed, the absorption and diffusion of fast electrons which resulted from their passage through relatively thick layers of solids. In all these experiments, however, solid films with a thickness below one micron were not investigated.

With the conception of the Rutherford model of the atom, many of these experiments were repeated with the object of determining the interaction of individual pairs of atomic particles. The critical experiments of this period involved the study of the scattering of electrons by individual atoms isolated in gases; and the study of collisions at large scattering angles by atoms or ions in solids. With the development of quantum mechanics and electron diffraction techniques the processes of small-angle elastic scattering in solids and inelastic scattering by gases were subjected to intensive investigation. However, there are at the present time insufficient quantitative data regarding the scattering of electrons in the range of small angles (10^{-4} to 10^{-2} radians) and small film thicknesses, *ca.* 10 to 500 Å, which are of greatest interest in the electron microscope problem, to permit a precise theoretical correlation of the observables in a micrograph with the optical constants of the electron microscope and the chemical composition of the specimens.

Marton¹¹³ and von Ardenne^{3, 5, 7} have carried out computations of the image intensities for various film thicknesses and beam voltages on the assumption that multiple scattering obtains throughout the range of specimen thicknesses of interest in the electron microscope problem. Comparison of image intensities predicted by these formulas with direct observations in the electron microscope shows that in the range of film thicknesses most frequently studied in the electron microscope (100 to 1,000 Å), the theoretical values are several orders of magnitude lower than the observed intensities. The reason for the discrepancy is evident when the multiple-scattering formula is compared, for example, with the experimental determination of angular scattering distributions by Kruppke.⁹⁹ The experimental curves show that multiple scattering is not fully developed until film thicknesses of the order of 10^{-4} cm are reached (for Al) and that for film thicknesses of the order of 300 Å, with electron velocities between 40 and 70 kv, the multiple-scattering formula fits the observations very poorly.

A second theory was postulated by von Borries and Ruska,⁴² who described the mechanism of image formation solely in terms of the unimpeded rectilinear transmission of electrons through solid films and the scattering resulting from electron diffraction. Although this simplifying assumption provides an explanation of image contrasts which is in better agreement with observations, the theory is inadequate since a great proportion of the scattered electrons is excluded from consideration. The qualitative deductions regarding the dependence of image contrast on electron beam accelerating potentials, which may be inferred from these early explanations, have been demonstrated experimentally by von Borries and Ruska,⁴⁵ Müller and Ruska¹²⁴ and Zworykin, Hillier and Vance.¹⁶²

A recent publication of Marton and Schiff¹¹⁶ represents the first step of a quantitative character in the correlation of image intensities with established physical theory concerning the scattering of electrons. Although satisfactory agreement is obtained in three examples between the values of film thicknesses computed with the aid of the scattering formulas and the values deduced by more direct methods, the general validity of the application of this method is questionable. The addition of elastic scattering intensities from individual atoms and ions requires modification to take into consideration the pronounced interference effects occurring in crystalline

solids, for it has been shown by Hillier and Baker⁸² and by Heidenreich⁷⁴ that reflections from crystal planes produce marked contrast anomalies. It is doubtful whether the laws of inelastic scattering of free electrons by individual atoms or ions may be extended to the case in which the same units are bound in a solid with the consequent obliteration of the discrete electronic energy levels.

Intimately associated with the problem of correlating the image intensities with the thickness of the specimen material are the effects of electron scattering on the resolving power of the objective lens. The magnitudes of both the spherical aberration and diffraction aberrations depend critically upon the angular distribution of the scattered electrons proceeding from the specimen through the objective lens. The chromatic aberration depends both upon the angular scattering and the velocity scattering. In consequence of these observations and also the possible presence of yet unrecognized aberrations, it has been difficult to set up a satisfactory criterion for the specification of the resolving power. The simple computations of von Ardenne^{5, 7} illustrate qualitatively the variation of these effects under different conditions of instrument constants and specimen materials.

(b) **Image Contours.** Displayed prominently in nearly all transmission electron micrographs with high resolution is the presence of a distinct bright halo about the boundary of well-defined particles or film discontinuities. Proceeding normally in the image across the boundary from an area of greater to an area of lesser intensity, the intensity rises sharply to a maximum in the vicinity of the boundary, then drops to a minimum (not always observable), thereupon rising to the constant value of the darker area representing the image of the more massive material. The interval between the extremities of this boundary anomaly is generally contained within 150 Å. The phenomenon is of some interest since it obscures the location of the physical boundary of the mass discontinuity in the specimen, thereby making it difficult to determine accurately the dimensions of a very small particles in a specimen.

Various factors have been considered as the origin of these contours. The resulting explanations have been made on the basis of the study of a small number of selected micrographs obtained under normal operating conditions and are not consistent with observations. The explanation of Borries and Ruska⁴³ is based upon the assumption that the effective width of the angular distribution curve of scattered electrons increases appreciably with the thickness and density of the specimen. As a consequence, the proportion of the scattered electrons passing through the peripheral regions of the objective lens aperture increases with the mass of the material, this resulting in an increase in the spherical aberration. In crossing the boundary from a thick film to a thinner one, there is an abrupt change in the magnitude of the spherical aberration. The hypothesis of Hillier,⁷⁹ in which it is assumed that there is an observable discontinuity in the chromatic aberration on traversing the boundary, leads to a similar conclusion.

Inspection of the effective widths of the contours occurring in any micrograph in which there are particles or plates in a wide range of thicknesses leads to the conclusion that the essential character of the contours is unaffected by the ratio of thickness or density of neighboring specimen areas. A comparison of the contours in micrographs of similar specimens obtained with different objective lens aperture diameters indicates that the aberration constants are not altered sufficiently, relative to each other, to change the character of the contours. It is evident that the variations of the spherical and chromatic aberration constants are not the primary factors underlying the contour phenomenon. Neither are these hypotheses consistent with the observations described in the second and third paragraphs of Section III (a).

From the observation of micrographs obtained in the transition from bright field to oblique dark-field illumination, the writer has concluded that electrons grazing the edge of a solid are deflected toward it. The experimental conditions are illustrated in Fig. 9. To the left of the point *A* in the object plane of the lens provided with the

diaphragm D , the entire illuminating beam of aperture δ would be transmitted through the lens in the absence of scattering. This is the region of normal bright-field illumination. The entire beam to the left of B would be excluded, this being the region of oblique dark-field illumination. Without scattering material in the object plane, the intensity distribution in the image plane in proceeding from the bright field to the dark field is represented by curve 1. With a film having an opening H in the object plane, the incident electron beam is scattered and an image of the film is formed in

FIGURE 9. Image intensity across the diameter of a hole in a specimen supporting film in the transition region between bright field and oblique dark field illumination. Curve 1: intensity transition in the absence of a film in the object plane; curve 2: expected intensity transition in the image of the specimen in the absence of contour phenomena; curve 3: observed intensity transition across the diameter of a hole in a cellulose-nitrate film.

the dark-field region by scattered electrons alone. The intensity distribution which would be expected in the absence of boundary effects is represented by curve 2. The observed intensity distribution, however, represented in curve 3, shows a clear *maximum at the edge of the opening adjacent to the bright-field area* and a *minimum at the edge adjacent to the dark-field area*. A qualitative explanation of these image borders in the transition region may be based upon the existence of a potential drop of the order of 10 volts across the boundary of solids. The assumption that the specimens are electrically charged during observation is unsatisfactory in accounting for the sharpness of the contour maximum and the observations that the character of the contour is maintained when a metallic specimen is connected to a source of known and variable potential.

Further verification of the hypothesis that electrons grazing the edge of a solid are deflected toward the material is provided by the study of the image contours in "out-of-focus" micrographs. Fig. 10a is a representative series of micrographs of an

opening in a cellulose nitrate film in which the focal length of the lens was *decreased* in steps from the value for which the film is considered to be in best focus. In addition to the normally observed contour maximum, a new maximum and minimum are developed. The normal maximum and the out-of-focus minimum deviate *away from* the edge (radially inward in Fig. 10a), whereas the out-of-focus maximum suffers a larger *inward* (radially outward in Fig. 10a) deviation.

FIGURE 10a. Typical micrographs in "out-of-focus" series: 1: plane of specimen in focus; 2, 3, 4: successive planes between specimen and lens in focus.

Curve 1 in Fig. 10b illustrates the deviation of the normally observed contour maximum at one edge of the hole in Fig. 10a as a function of the displacement of the focal plane of the lens from the plane of the specimen. The center of the sharpest intensity transition in the micrograph in which the specimen is considered in best focus is used as a reference point. Curves 2 and 3 represent the deviations of the minimum and maximum which become clearly distinguishable with a focal displacement in excess of *ca.* 20 microns.

Assuming that the electron beam grazing the edge of the film suffers a real deflection, the true location of the physical boundary in the specimen may be inferred from this figure. Extrapolation of the out-of-focus maximum, curve 3, into the object plane determines the region effecting the deflection and which, by hypothesis, is the physical boundary. In this case, the physical boundary appears to lie approximately at the minimum of the normal image contour. As it is, however, difficult to specify the micrograph which is in best focus because of the large focal depth, the absolute values of the focal plane displacements and consequently the point of intersection of the curve 3 with the specimen plane, are obscured to some extent.

The first maximum of the Fresnel straight-edge diffraction pattern, in accordance with the demonstration of Boersch,³⁹ should be found along curve 5 in the absence of modifying effects. A modifying effect, *viz.*, spherical aberration of the lens, has been suggested by Hillier⁵⁰ as the reason for the displacement and distortion of the diffraction pattern. On this account, the first maximum of the Fresnel pattern should be expected along curve 4. Within the limits of experimental error in obtaining the curves 1, 2, and 3, it is possible to identify curve 1 with curve 4 and thus to explain the main features of the observed boundary anomalies.

(c) **Resolving Power of the Electron Microscope.** The review of the lens aber-

rations included in Section II (b), (c), (d) may be considered as incomplete for lack of a discussion of the resultant of the aberrations on the resolving power of the lenses. This conclusion was neglected because the experimentally estimated values of the resolving power depend not only upon the magnitude of the lens aberrations described in Fig. 6 and equations (17) and (18), but upon their magnitudes as determined by the scattering of the electrons by the specimens used as test objects. All

FIGURE 10b. Deflections of intensity extrema. Curve 1: normal image contour maximum (measured); curve 2: out-of-focus minimum (measured); curve 3—out-of-focus maximum (measured); curve 4: first maximum of Fresnel straight edge diffraction pattern displaced by spherical aberration; curve 5: theoretical deflection of first maximum of Fresnel diffraction pattern.

statements which have appeared in the literature with respect to the experimentally attained optimum resolving power refer essentially to the resolving power exhibited in the normal electron microscope image. Adequate knowledge of the instrument constants and electron scattering to permit these experimental values to be related with the magnitude of the lens aberrations is lacking.

The resolving-power measurements which have been reported are based upon observations in selected micrographs of normal specimens, *i.e.*, particles mounted in or upon a supporting film. Resolved "points" in the specimen consist of small, neighboring, scattering particles in the specimen. The images of such scattering centers appear as dark spots in a bright background. In general, no criterion is given by means of which the "points" are considered to be distinguishable, and a correlation of these dark point sources in a bright background with the bright point sources considered in the formulation of the aberrations is not made apparent. In addition to the unsatisfactory theoretical basis of these measurements, they are inadequate for the comparison of the relative merits of instruments developed or employed by different workers. The reported resolving power values are aptly described as "practical" ⁸⁴ values, since pertinent data regarding the instrument constants and the in-

tensity distribution between the resolved points are not specified. Since the image contrast depends upon the effective apertures of the objective lenses as well as upon the relative densities and sizes of the "point" scattering centers, it might be assumed, for example, that the practical resolving power of 30 Å, reported by Hillier and Vance⁸⁴ from the observation of structural details revealed in a micrograph of Koroseal, would be lowered appreciably if they had obtained equivalent image definition in a micrograph of colloidal gold on a thin cellulose-nitrate film, the test specimen of von Ardenne.¹⁹

The metallic oxides proposed by Barnes and Burton²⁸ as test objects for the resolving power of electron microscopes may be useful as a qualitative comparison. From observations in micrographs of these materials it is difficult to formulate numerical values, even of the practical resolving power, which might be compared with the results of other workers. An examination of the numerous micrographs of magnesium oxide smoke which have been published indicates that the cubic crystal structure is maintained in the smallest particle sizes. The geometry of these crystals may be regarded as sufficiently simple to be used as test objects in the method of measuring practical resolving power suggested by the writer in the discussion of the results of von Kausche and von Borries⁹⁰ in Section VI.

Measurement of the effective widths of the intensity transitions in the image across the boundary of a dense and well-defined solid particle provides a measure of the resolving power if it is well above the range in which the image contours are observable. With the practical resolving power below *ca.* 100 Å, however, the intensity transitions are not monotonic, as described in Section III (b), and until a quantitative explanation of the contour phenomenon is available, the method is inapplicable.

The optimum resolving power is, of course, not attainable in the examination of the internal structures of thicker specimens (above *ca.* 2×10^6 gm/cm²). It is assumed that both the spherical and chromatic aberrations are enhanced by the increased scattering. The additional effects of spatial scattering within the specimen reduce the attainable resolving power further. A qualitative demonstration of these effects on the contrast and resolving power in the image is included in the earlier publications of Marton¹¹³ and von Ardenne.^{3, 5, 7}

An optimum practical resolving power of approximately 50 Å was attained in selected micrographs by several laboratories in 1939, *viz.* (50 Å³³; 50 Å¹³¹; 50 Å⁵¹). In the course of the last three years these limits have been extended in two respects. With considerable development in the power supplies, the stability characteristics of the instruments have been greatly improved. This has resulted in the attainment of an optimum practical resolving power of between 50 and 75 Å in the greater proportion of micrographs obtained under routine operating conditions. The practical limit in selected micrographs has also been reduced to some extent. The reported values, *viz.*, 25 Å⁴⁶; 22 Å^{20, 23}; 30 Å,⁸⁴ are difficult to compare with each other because of the somewhat arbitrary definition of resolving power. It is also difficult to compare the relative merits of different instruments in this respect or to estimate with great precision the improvement in the past three years.

On the basis of these achievements it might be inferred that the first phase in the development of the transmission electron microscope is completed. The initial objective of providing a practical instrument for investigations in the colloidal range of dimensions has been attained. The problems which have been overcome might be characterized as engineering difficulties, many of which have been solved in an empirical fashion. The second and perhaps more tedious phase of the development has already been initiated. One division of this development centers about the correction of the electron lenses. The immediate objectives may appear as lesser goals when compared with the initial success in surpassing the resolving limit of the light microscope by a factor of 20-50. The present problems are of a more fundamental character, and their complexity is well illustrated by the computations of the lens aberrations

by Glaser⁶⁶ and Dosse.^{56, 57} A second and perhaps more extensive division of the problems which require attention is the interpretation of the electron microscope images in terms of the physical theories of electron scattering and interference phenomena. Initial steps in this direction have been taken and are exemplified by the computations of Marton and Schiff,¹¹⁶ the observations of Hillier and Baker,⁸² and the discussion of the image-contour anomalies in the previous section. The preparation of specimens and the interpretation of the micrographs in terms of the techniques and the possible artifacts introduced in the specimens under the influences of evacuation and electron bombardment are problems which must be solved by investigators using the instruments in systematic studies wherein the results may be integrated with those of older and established methods.

Of immediate interest is the question of the *ultimate* resolving limit of present-day types of electron lenses. To the approximation in which the magnetic fields may be described by the function (4), Dosse⁵⁷ has estimated the limit which could be obtained with the customary type of pole piece construction and the limitations imposed by modern magnetic materials. Assuming a beam potential of 70 kv and a maximum attainable field of 10,000 gauss ($H = H_0$), he concluded that the optimum field half-width, d , lies between 1.6 and 2.9 mm. Within this range, the focal length and the spherical and chromatic aberration constants are all very near minimum values. The numerical values C_s (min.) = 0.92 mm; C_F (min.) = 1.57 mm; and f (min.) = 2.25 mm are considered as possible of attainment. The resolving limit, determined by the resultant of spherical aberration and diffraction under these conditions, and calculated by a formula of Scherzer,¹⁴⁶ is given by the relation

$$\delta_R = \lambda \left(\frac{C_s}{\lambda} \right)^{\frac{1}{4}} = 0.57 \times 10^{-6} \text{ mm, or } 5.7 \text{ \AA}$$

with an optimum lens aperture $\alpha = 6.7 \times 10^{-3}$ radian.

In view of the fact that the resolving limit depends upon the fourth root of the aberration constant C_s , it is evident that a reduction of the resolving limit below atomic dimensions is not likely to be attained by the present-day types of magnetic lenses, even if the maximum values of H_0 can be increased by the use of improved magnetic materials. Reduction of the spherical aberration constant by a factor of 16, for example, is effective in reducing the resolving limit only by a factor of 2. It is also pertinent to point out that the ultimate resolving limit of the electrostatic lens is not likely to fall far short of the magnetic lens in spite of the observation that the aberration constants are larger by a factor of between 5 and 7 than those of a corresponding magnetic lens.

The usefulness of a resolving power in the atomic range of dimensions has been discussed by Hillier⁸¹ and Schiff.¹⁴⁷ On the basis of a quantum mechanical calculation, Schiff concludes that contrast considerations would limit the resolving power in the image, so that individual atoms would not be revealed in the normal bright field image with 60 kv electrons if the atomic number is less than *ca.* 7. The semi-classical considerations of von Ardenne²¹⁴ indicate that both the Brownian motion and recoil from electron bombardment would be effective in obscuring the image of a freely suspended atom. However, with an atom embedded in a solid film, his computations indicate that the amplitude of the motion is below 1 Å. It may be concluded from these discussions that if the lenses can be adequately corrected, the method of dark-field illumination will provide decided advantages in the atomic range of dimensions in much the way it has proven valuable in colloidal investigations with the light microscope.

IV. PRINCIPLES OF CONSTRUCTION OF AN ELECTRON TRANSMISSION MICROSCOPE

The first two-stage magnetic electron microscope was constructed in 1931 by Knoll and Ruska.⁹⁷ From a study of its characteristics, Ruska^{133, 134} was able to

construct a second instrument in 1934, the resolving power of which later surpassed by more than an order of magnitude the resolving limit of the light microscope. On this continent, the development was initiated at the University of Toronto with the construction in 1938 of a microscope by Prebus and Hillier.^{130, 51} These and other experimental developments^{19, 111} have culminated in the construction on a commercial basis of electron microscopes for general laboratory use by the Siemens and Halske AG in Germany,⁴¹ the RCA Manufacturing Company^{84, 115} and the General Electric Company.²⁶

Although they vary considerably in construction detail, the principal features of all magnetic electron microscopes in operation at the present time are sufficiently similar to be adequately illustrated by a description of the electron microscope constructed by the writer at the Ohio State University in 1940. At that time, it was common practice to set as an objective the attainment of a resolving power of 10 Å. The dimensions of an apparatus which would permit the observation and recording of images exhibiting this resolving power were estimated in terms of the resolving power of the human eye, of commercially available photographic emulsions, and of fluorescent screens prepared by customary techniques.

Assuming a resolving power of 0.1 mm at a viewing distance of 25 cm for the normal human eye, the necessary magnification of the electron microscope image exhibiting a resolving power of 10 Å, in order that all of its detail may be revealed, is given by the ratio of 0.1 millimeter to 1 millimicron, or 100,000 diameters. Direct observation of the electron microscope image at this magnification is, however, impractical. It is more convenient to secure a record of the image at a lower magnification and to enlarge the micrograph subsequently by customary photographic procedure to values for which the finest details can be seen by the unaided eye. With a photographic plate of fixed dimensions, the area of the specimen recorded in one exposure varies inversely as the square of the magnification. Of equal or greater importance is the fact that the necessary current density in the specimen for a given image intensity varies inversely as the square of the magnification. For these reasons, it is desirable to record the image at the smallest possible magnification. This requires the selection of an emulsion of high resolving power. Because of their relatively low sensitivity to light and their fine grain, lantern slide plates have been used extensively. These have an estimated resolving power of 0.01 mm. It has been demonstrated by von Ardenne⁸ that the resolving power of an emulsion depends not only upon its grain size, but also upon its thickness, and upon the accelerating potential of the electron beam. It is, therefore, not permissible to assume that the resolving power of an emulsion is the same for electrons as it is for light. Speed and contrast characteristics also cannot be inferred from the manufacturers' characteristics. Some speed and contrast measurements with electrons have been reported by Marton¹¹⁴ and by Baker, Ramberg and Hillier.²⁷ Assuming, however, that lantern slide plates with the above-indicated resolving power are used, it is apparent that an image exhibiting a resolving power of 10 Å would have to be magnified 10,000 diameters in order that all of its detail be recorded. This number represents the minimum necessary magnification for the implied, but as yet unattained, resolving power. With the highest resolving power now attained, *ca.* 25 Å, a magnification of 4,000 diameters is adequate for photographic recording.

The second factor to be considered in the choice of the minimum necessary magnification is the technique employed for focusing the images. A procedure which has been used extensively consists in focusing the image on a fluorescent screen with the unaided eye. Visual focusing is carried out by using an illuminating beam with an aperture which is greater than that required for optimum resolution. This results in the observation of an intense image in which the resolution is low, and which can, therefore, be focused accurately. Before making an exposure, the beam aperture is reduced. This reduces the intensity, but increases the resolving power. By proper

choice of apertures in the above two steps, it has been found possible to obtain an accurately focused micrograph exhibiting optimum resolution. Choice of the proper apertures is governed by the *relative focal depths* in the two cases.

If it is assumed, for simplicity, that the resolving power is the sum of spherical aberration and lens aperture diffraction as implied in the formula

$$\delta_R = C_s \delta^3 + \frac{\lambda}{2\delta} \quad (20)$$

the focal depth T is given by the relation

$$T = C_s \delta^2 + \frac{\lambda}{2\delta^2} \quad (21)$$

If, consistent with the discussion in the first four paragraphs of Section III (a), it is further assumed that the image definition is governed essentially by the aperture of the illuminating beam, optimum resolution is attained when

$$\delta = \left(\frac{\lambda}{6C_s} \right)^{\frac{1}{3}} \quad (22)$$

If the recorded image is to be accurately focused, the focal depth obtaining during the exposure must be *equal to or greater than* the focal depth obtaining when the image is being focused.

It is apparent from inspection of equations (20) and (21), that the value of δ for which T is a minimum is greater than the value of δ for which δ_R is a minimum. Hence, the focal depth under conditions of optimum resolution is greater than the minimum focal depth. Of greater significance is the result that there is a second and larger value of δ for which the focal depth is equal to the focal depth under exposure conditions. The latter value of δ is the limiting value which may be used during visual focusing if the recorded image is to be in best focus. On the basis of these simple formulas, numerical values may be estimated. Assuming, for example, that $\lambda = 5 \times 10^{-9}$ mm (50 kv electrons), and $C_s = 100$ mm, optimum resolution is obtained when $\delta = \delta_{opt} = 1.7 \times 10^{-3}$. The focal depth in this case is $T = 1.0 \times 10^{-3}$ mm. The computed limiting value of δ , *viz.*, $\delta_{lim} = 2.9 \times 10^{-3}$.

It is evident from the results of many workers that the "practical" resolving power, measured as the distance between "just distinguishable" small particles supported in the usual thin film, remains sensibly constant if the aperture of the illuminating beam is reduced by as much as a factor of order 10 below the above computed value for optimum resolution. This result indicates that the effective aperture of the electron beam scattered by the normal supporting film is of the order of 1×10^{-3} and consequently determines both the resolving power and focal depth. It is reasonable, therefore, to assume that the focal depth is essentially independent of the aperture of the illuminating beam in the range below δ_{opt} , and has a value close to that computed from formula (19) with $\delta = \delta_{opt}$. In the higher range of δ , where the resolution is determined primarily by spherical aberration, formula (19) may be regarded as reasonably accurate. It follows that the computed numerical values of δ_{opt} and δ_{lim} serve as a useful guide in selecting the proper aperture of the illuminating beam to assure sharply focused micrographs.

If the selected value of δ for visual focusing is in the neighborhood of 10^{-2} radian and an electron gun is used which produces a beam with discontinuities in the angular intensity distribution, multiple images may be observed in the micrographs. The occurrence of such multiple images is conclusive evidence that the selected aperture is excessively large. Since there are other factors, some of which are not clearly understood, which prevent the consistent attainment of the highest resolving power of

which a given lens is capable, it is difficult to determine the best value experimentally. It is, of course, desirable to use the largest permissible value in order to obtain greatest image intensity. In the course of preparing several hundred micrographs, it became apparent to the writer that the *average* of properly focused micrographs does depend upon the aperture chosen for visual focusing, and that the average is greater by adhering to apertures in the neighborhood of the computed limiting value.

Assuming the correctness of the numerical value 1.7 for the ratio $\delta_{\text{opt}}/\delta_{\text{lim}}$, the ratio of the resolving powers in the two cases is given approximately by the factor 1.7. Consequently, the minimum necessary magnification required for accurate visual focusing, with the unaided eye, of an image exhibiting a resolving power of 10 Å is 60,000 diameters. With the highest attained resolving power at the present time, *ca.* 25 Å, a magnification of only 23,500 diameters is necessary.

Because of the large difference between the magnification of 23,500 diameters required for accurate visual focusing and the magnification of 4,000 diameters required for photographic recording, the advantage of using an ocular to focus the image on the fluorescent screen is evident. The majority of the instruments now in use were designed for high electronic magnifications to avoid the use of an ocular. By the use of fine-grained fluorescent screens, however, it is possible to use a magnifying lens for visual focusing. The permissible magnification depends upon the type of screen. In the instrument constructed by the writer, the fluorescent screen may be viewed with an ocular magnifying it up to 5 diameters. Although the instrument was initially designed for higher magnifications, the images are focused upon the fluorescent screen at a magnification of approximately 7,500 diameters, and are viewed with aid of the ocular at a magnification of 37,500 diameters. Although these are above minimum necessary values, they provide relief from eye-strain. In the new instrument recently developed by the RCA Manufacturing Company, even smaller electronic magnifications are used. In both this instrument and the electrostatic electron microscope of the General Electric Company, the fluorescent screens may be magnified from 10 to 20 diameters without loss of detail in the images. Von Ardenne was perhaps the first to advocate the use of an ocular lens for visual focusing. He has used a grainless single-crystal fluorescent screen upon which the image could be observed, with full content detail, at the much greater magnifications provided by a large-aperture microscope objective lens.

There is a definite advantage in using the previously described two-step procedure in focusing micrographs. The image observed in the first step has much greater intensity than the image which is recorded. If this procedure is employed, the minimum necessary electronic magnification in an apparatus provided with a suitable fine-grained fluorescent screen and ocular may be estimated in terms of the resolving power of the selected photographic emulsion alone. This will result in an instrument of smallest dimensions.

Having selected a value for the necessary electronic magnification to permit the recording of the smallest image details, the length of the instrument from the objective lens to the final image plane depends upon the focal lengths of suitable lenses, and the number of these to be used. The selection of lenses is at present somewhat arbitrary. Objective lenses with focal lengths between 3 and 5 mm have been found satisfactory for the attainment of a resolving power below 50 Å. Although von Ardenne has reported the use of an objective lens with a focal length less than 1 mm, the construction of such a lens involves more serious mechanical difficulties. Such lenses are entirely satisfactory, however, for enlarging the images provided by an objective lens. In this application, the spherical aberration constant is of minor importance. The distortion of the lens requires more careful consideration.

An instrument consisting of a single lens would have to have a length of many meters to provide a sufficiently great electronic magnification. A reduction to an apparatus length of less than one meter is possible by constructing a two-stage instru-

ment in which the image formed by one lens, the *objective*, is enlarged by a second or *projector* lens. The apparatus length of a two-stage instrument may be easily computed (see also ^{20b}) in terms of the final magnification and the focal lengths of the lenses which are to be used. With an objective lens of focal length f_1 ; a projector lens of focal length f_2 distant d from the objective (both lenses regarded as thin); and an apparatus length L (distance from objective lens to final image plane), the final magnification M is given by the relation

$$M \simeq \frac{d(L + f_1) - d^2 - L(f_1 + f_2)}{f_1 \cdot f_2}$$

With fixed focal-length lenses, maximum magnification is obtained when $d = (f_1 + L)/2$. With the lenses disposed in accordance with this condition, the magnification is determined by the relation

$$M \simeq \frac{L^2}{4f_1 f_2}$$

Thus, assuming the use of a 4-mm objective lens and a 1-mm projector lens, magnifications of 4,000 and 10,000 diameters may be obtained with apparatus lengths of 25 cm and 40 cm, respectively.

In the instrument constructed by the writer, the projector lens is a doublet. This permits the attainment of the magnification of a two-stage instrument with the use of longer focal-length lenses. The advantage of longer focal-length lenses in the projector is the attainment of a larger field of view for images observed at lower magnifications. This advantage is offset, however, by the necessity of careful adjustment of the relative focal lengths of the lenses to overcome image distortion.

This instrument is shown in Figs. 11a and b. The source of the electrons is a heated tungsten hairpin filament F in the electron gun G situated at the upper end of the apparatus. The electrons are accelerated by application of a negative potential, variable from 10,000 to 90,000 volts (up to 300,000 volts in the high-voltage RCA microscope ¹⁸²) to the cathode of the gun at H . The divergent electron beam passing through the opening in the anode is converged by the magnetic field of the coil C serving as a *condenser* lens. An image of either the source or of the "cross-over" may be focused in the plane of the specimen, situated at the lower end of the cartridge L immediately above the *objective* lens O . Under these conditions, both the aperture and intensity of the illuminating beam are at a maximum. The aperture is determined by the ratio of the diameter of the condenser lens aperture diaphragm to the distance between the center of the condenser and the specimen. The aperture and image intensity may be decreased by either of two methods. The aperture diaphragm may be replaced by one of smaller size, or by a dark-field stop. Several diaphragms of different diameters are fastened in a movable slide A_c , controlled from the exterior. Alternatively, the beam aperture may be decreased by raising or lowering the focal plane of the "cross-over" image.⁴³

The electron beam, after transmission through the specimen, is converged by the magnetic field between the pole pieces of the objective lens, thereby forming an image of the specimen at low magnification on a fluorescent screen I . After surveying this image, a selected area may be adjusted to fall over a small opening in the fluorescent screen. This area is then enlarged to a final magnification in the neighborhood of 7,500 diameters by the projector lenses P_1, P_2 . The final image may be viewed on the fluorescent screen S through the window W . A photographic plate, inserted under the fluorescent screen from the compartment PM , is exposed by removing the fluorescent screen.

Since the entire optical system is in a vacuum, all mechanical motions of the

specimen, the lenses, electron source, and photographic plate must be transmitted from the exterior through vacuum-tight joints. Most of these joints are provided with flexible metallic bellows, one of which is shown at *B*.

Routine operation of this instrument is in many respects simpler and more rapid

FIGURE 11a. Magnetic electron microscope constructed in the Radiation Laboratory of the Ohio State University in 1940.

than the operations of a high-power light microscope. Specimens may be inserted and ready for observation in an interval of from five to ten minutes. Photographic exposures rarely exceed 3 seconds. In this apparatus five two-inch square micrographs may be secured on one plate. An exposed plate may be replaced, and the system re-evacuated in less than four minutes. With improved air "locks," plates and specimens may be interchanged even more rapidly.⁸⁴

In the photograph of the electron microscope illustrated in Fig. 11a there may be seen a second plate compartment, or camera, situated immediately over the projector lens system. This plate magazine has been installed for the purpose of recording the diffraction patterns of *selected microscopic areas* in the specimens normally studied

with the electron microscope. The principle of integrating the electron microscope with the diffraction camera may be considered as a development of the suggestion of Boersch.³⁶

With the use of an electron gun which provides an intense beam of small initial cross-section and small aperture, it is possible in this instrument to restrict the illumi-

FIGURE 11b. Diagrammatic sketch of the electron microscope in Fig. 11a.

nated area of the specimen to a circle only a few microns in diameter. Even greater reduction of the illuminated area would be possible by the use of a specially designed condenser lens system such as described by von Ardenne.²² Conversion of the optical system of the electron microscope to serve as a diffraction camera necessitates only the replacement of the normal condenser aperture diaphragm by one of small diameter. The new diaphragm serves as an electron source for the diffraction pattern and an image of it, together with the entire diffraction pattern, may be focused in the first image plane by adjustment of the focal length of the objective lens. Micrographs of the area in which the diffraction pattern is formed may be recorded either before or after recording the diffraction pattern without disturbing the specimen or the vacuum in the apparatus. It is also sometimes convenient to utilize the projector lens of the microscope to form highly magnified images of portions of the diffraction pattern. These may be recorded in the lower camera, thereby facilitating the measurement of intensity contours of the diffraction bands or spots.

In the apparatus employed by the writer at the present time, it is not possible to identify the area producing the diffraction pattern to within closer limits than

approximately 40 microns. In consequence, the electron gun is adjusted to provide an illuminated area of this diameter. A more precise identification of the specimen area studied by diffraction is considered possible in the design of a new instrument.

An electron diffraction attachment for both transmission and reflection studies has been developed and described by Hillier, Baker and Zworykin.⁸³ In this apparatus, the specimen holder may be taken out of its position above the objective lens and inserted between the lenses of a double projector. This permits the electron microscope to be used either as electron microscope or as a diffraction camera. In the latter case, the first projector provides a point source of electrons, and the second forms an image of this source together with the diffraction pattern on the final image plane.

Description of a magnetic electron microscope is incomplete without reference to the power supplies providing the current for the lenses and the accelerating potential for the illuminating beam. Since the chromatic aberration of this type of microscope is enhanced by fluctuations in the accelerating potential and lens currents, it is necessary to maintain these constant within very close limits.⁸⁴ Power supplies with special stabilizing devices have been developed for these instruments and may thus be considered as integral parts of them.

Storage batteries have been used successfully by many workers to serve as current sources for the lenses. They are, however, unsatisfactory in several respects. As a battery is essentially a constant-voltage source, long periods are required to establish temperature equilibrium in the coils of the lenses and control rheostats in order to ensure current constancy. Voltage drift of undesirable magnitude over periods exceeding one or two minutes are unavoidable without excessively expensive batteries. Both of these difficulties are overcome by the use of an electronic rectifier and current regulating system. Very high current stability (variations less than one part in 50,000) for short intervals and satisfactory stability over indefinitely long periods can be obtained from a stabilized power supply of the type developed by Vance.¹⁵⁷ Power supplies for the lenses may eventually be eliminated entirely through the use of magnetostatic or permanent-magnet lenses. Although relatively poor results were obtained with the experimental magnetostatic lens of von Borries, Ruska, Krumm and Müller,⁴⁷ a more careful design with the use of modern permanent magnet materials will result in useful lenses.

Stabilization of the high-voltage system presents a more difficult problem. In a high-voltage system consisting of a transformer and rectifier, there exist three sources of variations in the accelerating potential, *viz.*, variations in the voltage applied to the transformer primary, ripple, and variations in the output current. Fluctuations in "line" voltage can be reduced to negligibly small values by a number of methods, including the use of special generators, and special regulating transformers of the type manufactured by the Sola Electric Company. Ripple in the rectified voltage can similarly be reduced to small values by the use of capacity-resistance or -inductance filtering. The third source of voltage variation is more difficult to control. It is the result of electron current variations in the electron gun of the instrument which may be due to temperature variations affecting the specific emission from the filament and the interelectrode spacings in the cathode, and to changes in the emission constants of the filament.

The most elegant solution to this problem is the radio frequency power supply developed by Vance.¹⁵⁷ Since the necessary filter condenser capacity for a given ripple attenuation varies inversely as the frequency, the use of radio frequency effects a very large reduction in the capacity and consequently the physical size of the filter system. Of greater importance is the reduction of the time constant of the filter system. This makes it possible to detect and amplify very small variations in the potential at the cathode of the electron gun, and to compensate for any variations by application of a commensurate and opposed voltage variation in the primary of the high-voltage transformer.

A 60-cycle high-voltage system stabilized against the three sources of variations has been developed by the writer. A description of this circuit, illustrated in Fig. 12, may prove interesting to those unfamiliar with the high-frequency techniques required in the construction of a radio frequency system. The secondary of the high voltage transformer S and the low potential terminals of the filter condensers C_1 , C_2 are connected together and insulated from ground. A high resistance R_3 (400 megohms) in series with the lower resistance R_4 (0.5 megohm) are connected in parallel with the electron microscope gun represented by M . By this means, a small

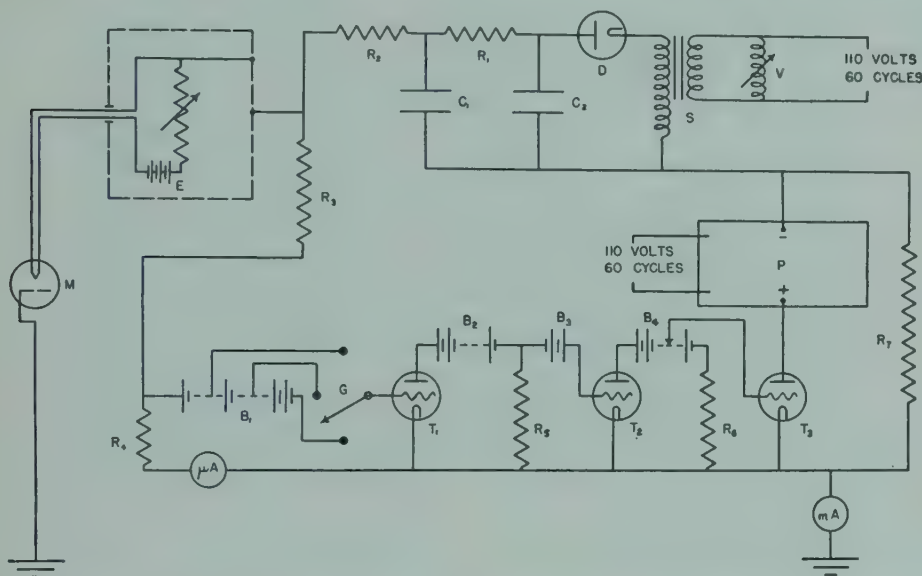

FIGURE 12. Circuit of the stabilized 60-cycle high-voltage power supply used with the Ohio State University electron microscope.

fraction of the total accelerating potential is impressed on the grid of the detector tube T_1 suitably biased with a battery B_1 . Voltage variations detected by T_1 are amplified with high-voltage gain and fed to the grid of the power tube T_3 . An independent, unregulated power pack P (2,000 volts d-c) in series with the output tube and resistance R_7 provides a compensating voltage (within a range of 1,500 volts) by raising or lowering the potential of the low-voltage terminal of the rectifier and filter system relative to ground. By use of this degenerative type of stabilizer (voltage gain 50,000) the time constant of the 60-cycle filter system is determined by the external surface of the system relative to ground. Although it has not been possible to effect a ripple reduction commensurate with the voltage gain of the amplifier on the assumption of a zero time constant, an adequate reduction, *ca.* 100 to 1.5 volts, as measured with a vacuum tube voltmeter, is provided. Reduction of the effect of slow drift is more effective since in this case the time constant plays a minor role. Over prolonged periods, however, there is an undesirable voltage drift, attributed to EMF drops in the batteries of the circuit.

A highly stabilized high-voltage system is entirely unnecessary with the electrostatic transmission electron microscope of the type described by Mahl^{103, 105} and Bachman.²⁶ As the electrostatic lenses require no current, the additional power supply required for the lenses of the magnetic microscope is eliminated. For these reasons, the electrostatic microscope is much simpler and less costly in construction and has stability characteristics exceeding those of the magnetic electron microscope. The principles of the instrument constructed in the AEG Laboratories are illustrated in Fig. 13, reproduced from a publication of Mahl.¹⁰⁵ Electrons produced in

the cathode G are accelerated up to 50,000 volts to provide an illuminating beam emerging from the anode diaphragm B_1 . A condenser lens has been avoided by suitable design of the cathode of the electron gun. The objective lens L_1 , with the focusing electrode at the potential of the cathode of the gun, is provided with an aperture-limiting diaphragm in the form of a very small opening ($\frac{1}{10}$ millimeter in diameter) in the lower electrode which is at anode potential.

FIGURE 13. Schematic cross-section of the transmission electrostatic electron microscope described by Mahl^{103,105}. (Left) Lens electrode connections for lowest magnification; (right) lens electrode connections for highest magnification. An intermediate magnification is obtained by connecting the focusing electrodes of both projector lenses to cathode potential.¹⁰⁵

The double projector lens L_2 , L_3 , permits the specimen to be observed on the final fluorescent screen S at any one of three magnifications. These are fixed by the geometry of the instrument. A large area of the specimen may be observed at low magnification, *ca.* 1,000 diameters, by connecting the focusing electrode of the lens L_2 to the cathode and the focusing electrode of the lens L_3 to the anode as shown in Fig. 13 (left). A higher magnification, *ca.* 9,000 diameters, is obtained by interchanging the connections as shown in Fig. 13 (right). Intermediate magnification is obtained by connecting the focusing electrodes of both lenses to cathode potential. By use of the double projector lense, with these interchangeable connections, one of the main disadvantages of the electrostatic microscope with fixed focal length lenses is eliminated.

Independence of the chromatic aberration from fluctuations of the beam accelerating potential is demonstrated in the micrographs shown in Figure 14. The former was obtained with an unfiltered potential from a half wave rectifier, the latter with a filtered potential. It is evident from the equivalence of the image definition in these two micrographs that a total voltage fluctuation of 50,000 volts in each cycle has an imperceptible effect on the resolution.

Although the resolving power reported by Mahl, 80-100 Å, is somewhat less than the resolving power attained with the present-day magnetic electron microscopes,

there is no apparent reason for concluding that the limit of resolution of one is superior to the other in the same ratio. Indeed, the correction of the electrostatic lens may be a less difficult task, since the axial field is more intimately related to the geometry of the electrodes than is a magnetic field to pole piece geometry.

The limitation on the maximum attainable beam potential is more serious. This depends upon the greatest field which can be maintained between the closely spaced electrodes in the lenses. With the technique described by Mahl, the limit is about

FIGURE 14. Micrographs of magnesium-oxide smoke obtained with the electrostatic electron microscope: (left) with the electron beam potential varying over a range of 50,000 volts; (right) with a filtered beam potential. This comparison shows the insensitivity of the electrostatic electron microscope to fluctuations in the accelerating potential of the illuminating electron beam.¹⁰⁵

60,000 volts. This is, of course, within the range of beam potentials commonly used at the present time with the magnetic electron microscope for which optimum contrast and resolution are obtained in the study of colloidal materials. This type of instrument could be used with equal success in many of the problems studied with the magnetic microscope. In view of its greater simplicity of construction and greater stability, it will probably be found more satisfactory in many applications, when developed further.

A commercial instrument of this type has been developed by the General Electric Company.²⁶ High resolving power has been sacrificed in this instrument in the interests of compactness, simple construction and stability of operation. In the many problems in which structural details requiring a resolving power below *ca.* 200 Å are of secondary interest, the application of this instrument is probably more economical than that of the magnetic electron microscopes now available. This instrument should prove particularly valuable to those research workers who are accustomed to using the light microscope near its limit of resolution.

V. THE PREPARATION OF SPECIMENS

Specimens to be studied in a transmission electron microscope differ in many respects from the type of specimen commonly studied with the transmission or ultra-microscopes. Since they are mounted in a vacuum chamber for observation, they must be free of volatile liquids. This requirement precludes the possibility of observing animation or reactions in liquid media. Whereas specimens of relatively

great thickness (several microns) are commonly prepared for observation in the light microscope and can be studied layer by layer with a high-power objective lens, the high resolving power of the electron microscope can only be exploited if the total thickness of the specimen together with its supporting slide and cover slip is below 50 millimicrons in thickness. As a consequence, the commercially available electron microscopes are of questionable value in the study of such specimens as cut sections. This limitation may be overcome by the use of other electron optical instruments less well known at the present time. It is evident that resolution surpassing the light microscope is possible by preparing wedge sections as described by von Ardenne¹⁴ * and examining these in a high-voltage electron microscope of the type developed by Zworykin, Illier and Vance¹⁶² and by Müller and Ruska.¹²⁴ Even under these conditions, however, the resolving power does not approach the value obtained with the thinner specimens and lower-voltage instruments.

The conclusions of von Ardenne¹⁰ regarding the possibility of observing living structures in the electron microscope are not considered as final. The killing effect of the electron radiation considered by him may not apply to small living organisms such as viruses which absorb relatively little energy from the illuminating beam compared to larger structures, such as bacteria and cells.

There are certain obvious ideal requirements to be satisfied by a material which is to serve as an electron microscope "slide." In the form of a thin film which is sufficiently transparent to the illuminating electron beam (thickness \times density = *ca.* 1×10^{-6} gm/cm²) the molecular or crystal structure should be below the limit of resolution of the microscope. It should have sufficient tensile strength, flexibility and elasticity to withstand the mechanical strains resulting from the distortions and electrical charges of the specimen materials which may occur during preparation and observation. Resistance of the material to the action of the common chemicals and organic solvents generally employed in colloidal and biochemical preparations is highly desirable. From a practical standpoint, it is essential that the films can be prepared rapidly and under conditions permitting films of given properties to be easily reproduced.

Although many types of glass may fulfill the mechanical and chemical requirements to a satisfactory degree, no successful techniques have been developed for the preparation of sufficiently thin and uniform films. Oxide films of the lighter metals may come into use as the need for improved resistance to chemical action and high temperatures increases. The suitability of aluminum oxide films for this purpose has been demonstrated by Haas and Kehler.⁷⁰ Silica films, deposited on a structureless base by evaporation in a vacuum chamber, have been found suitable for specimen supports by Heidenreich.⁷⁴ These films will undoubtedly find extensive application in the future.

A small number of thermoplastic polymers, however, have been used almost exclusively in both electron diffraction and electron microscope studies. Thin structureless films of these materials are easily prepared by permitting the evaporation of the solvent from a dilute solution spread in a thin layer on the surface of either a liquid or solid. It has been difficult to select a polymer with optimum properties for this application on the basis of the known physical and chemical properties of these materials in bulk form. Negligible surface properties are highly significant if a material exists in the form of a film with a thickness less than the length of its molecules.

In the course of testing the suitability of a variety of polymers for this application, it has been possible to verify the application of the observations of Ott¹²⁶ to the case of these extremely thin films. The mechanical properties of films formed from cellulose nitrate samples of different viscosities improve perceptibly with increasing vis-

* See also paper by Richards, A. G., Anderson, T. F., and Hance, R. T.—*Proc. Soc. Exp. Biol. and Med.*, 51, 148 (1942).

cosity up to approximately 20 seconds (ASTM). The most satisfactory films are obtained from a sample of uniform molecular weight. Films produced from mixtures of low and high viscosity samples have mechanical properties equivalent to the films produced from the low-viscosity component. As these observations probably apply to any polymer, they may in part account for the difficulty in finding suitable synthetic polymers for this purpose. The natural polymers have in general a more uniform distribution of molecular weights.

Although other liquids are not excluded, it is very convenient to use water as a base upon which to form films. This choice restricts the variety of solvents which may be used to those which are insoluble or only slightly soluble in water, spread readily on water, and have a lower specific gravity than water. The evaporation rate should be low enough to permit a drop of solution placed on the surface of the water to spread to a layer of uniform thickness. Cellulose nitrate dissolved in amyl acetate has been used most widely.

Although varying in details from the methods of other workers,^{21a, 137} the following procedure for preparing plastic specimen supports has been found reasonably satisfactory in the laboratory of the writer. By means of a medicine dropper, a single drop of 2 per cent solution of cellulose nitrate of 20-second viscosity and containing a small proportion of plasticizer (dibutyl phthalate) is gently lowered to the surface of a shallow vessel filled to the brim with distilled water. The solution spreads rapidly to cover approximately half of the exposed water surface, whereupon the solvent evaporates, leaving a fairly uniform film of cellulose nitrate in the center of the vessel. The uniformity and cleanliness of the film depend upon the cleanliness of the water surface before the solution is deposited. By using a "Pyrex" pie plate with the flange ground flat and covered with paraffin, it is possible to sweep the surface clean with glass or chromium bars immediately before a film is to be deposited.

If the suspended area of the dried film has a diameter in excess of approximately 0.1 millimeter, it is likely to rupture when exposed to the electron beam. The film is therefore suspended over the surface of a fine screen before removal from the surface of the water. In order to reduce the contamination which is difficult to avoid in manipulating the small mesh discs normally mounted in the instrument, it is advantageous to remove the film from the water surface on a relatively large section of mesh (1 cm²) which previously has been cleaned with dilute acid and rinsed thoroughly in distilled water. A rectangular section of mesh is immersed below the film with forceps and raised from beneath a selected film area. On removal from the vessel, excess water may be drained away with a folded edge of filter paper. When completely dry, the mesh supporting the film may be cut into smaller rectangular sections with shears. After mounting the material to be studied, suitable areas may be selected with the aid of a light microscope. Circular discs, containing the selected areas, may then be cut with a hollow ground punch without injury to the film.

With the technique developed by Schaeffer and Harker¹⁴³ it is possible to prepare satisfactory thin films of the synthetic plastic, polyvinyl formal, (Formvar, Shawinigan Products Corporation, New York City) by using mica or glass as a base from which to evaporate the solvent. This material apparently has somewhat better mechanical properties and is less susceptible to ageing. It is particularly well adapted to the preparation of replica specimens which will be described in Section VI.

As none of the plastics which have been used has adequate resistance to chemicals and organic solvents, it is preferable to suspend the material to be studied in water or to disperse it from a dried sample. Undesirable coagulation of colloiddally dispersed specimen materials, which occurs as a result of the evaporation of the water in which they are initially suspended, is frequently difficult to avoid. It may be diminished by the addition of a wetting agent to the suspension. Its type and concentration must be selected with due consideration for the amount of solid material which re-

mains on the film after evaporation. It is also possible in some instances to prevent flocculation by addition of an electrolyte in an amount just sufficient to be completely absorbed on the particles. This has been found successful in the preparation of clay mineral specimens. A novel method of overcoming coarse flocculation has been suggested by von Ardenne.¹⁵ The specimen holder is mounted on the end of a vibrating rod (tuning fork) during the drying period. Addition of a monolayer on the surface of the prepared film to make it hydrophylic, as suggested by Schaeffer and Harker,¹⁴³ is probably a more satisfactory general procedure for the prevention of coagulation. The development of this procedure should also prove of value in the preparation of biological specimens which are suspended in normal saline solution.

Satisfactory dispersions of dry powdered materials are in general even more difficult to prepare. Several methods which have been used in the laboratory of the writer in the study of pigments yield specimens in which an appreciable proportion of the particles appear isolated. A thin plastic film is deposited on the surface of a glass slide which previously has been coated with gelatin and cooled in a refrigerator. Powdered material may then be dusted on the film and dispersed by means of a luminous discharge from a Tesla Coil. Although the film is ruptured by this discharge, satisfactory dispersions are obtained in selected areas. The method fails entirely for materials which do not adhere to the film. In the latter case, the powder is placed in a bottle which is saturated with the vapor of the plastic solvent. After the mouth of the bottle is covered with the coated side of the glass slide, the bottle is shaken vigorously. A thick deposit of powder is formed on the film, softened by the solvent vapor. On removal of the excess deposit by tapping the slide, the dried film retains a covering of partially embedded and dispersed particles.

After mounting the powder on the film by either of the above or yet other methods, the film is refloated on a warm water surface, specimen side upward, by teasing the gelatin from the glass slide. The gelatin is subsequently washed away and the film retrieved on a mesh in the usual manner.

Many materials may, of course, be dispersed in solvents containing a small proportion of cellulose nitrate or other film-forming material. Although this procedure simplifies the preparation of the specimen, the difficulty of coagulation is not in general avoided and the true dimensions of the particles may be obscured by the enveloping film.

VI. SOME APPLICATIONS OF THE ELECTRON MICROSCOPE

(a) **In the Physical Sciences and their Technical Applications.** The optimum resolving power of the transmission electron microscope can be exploited to provide significant results from the determination of the dimensions of solid colloidal particles normally suspended in liquids or gases. From among the large number of publications in which the appearance of various types of the colloids have been illustrated, only a few examples can be selected for review. These demonstrate the usefulness of the instrument, its relationship to the established indirect methods of observation, as well as some of the difficulties which have been encountered in the interpretation of the micrographs. Perhaps the most fundamental problem in this field is the establishment of the three-dimensional geometry of small particles from the data provided in a two-dimensional image.

The determination of the geometrical form of particles which depart but little from spheres or from the circular shape in the plane of the specimen is discussed in a paper by Kausche and von Borries⁹⁰ concerning the sizes and shapes of the particles in some commercial colloidal gold preparations. The writers assume that crystallites in the colloidal range are bounded by plane faces intersecting in geometrical lines and that these would be revealed as such in the image provided by a microscope with infinite resolving power. On this basis they consider the effect of a finite resolving

power in obscuring the geometrical boundaries. Their conclusions are based on the approximation that the geometrical boundaries in the object appear in the image as boundaries of finite width, within which the image intensity falls continuously from the intensity of the background to the intensity of the particle. The effective width of the boundary is considered equal to twice the practical resolving power, δ_R , of the instrument and the physical boundary of the particle at a point midway between the particle and background intensities. In consequence of the finite resolving power, the image boundary at the intersection of two straight lines is rounded. It is assumed that the curvature of the rounded corner is circular, the arc being tangent to the intersecting edges at a distance δ_R from the point of intersection inferred by geometrical construction. In the case of a symmetrical particle (in the plane of the specimen), the rounded corners tend to obscure the crystalline shape. In accordance with the criterion of the writers, recognition of departure from circular shape is possible if the length of the straight portions of the edges in the image is equal to or greater than the length of the chord between the extremities of the arc. Fig. 15

FIGURE 15. The image of a symmetrical figure with n corners or equal straight edges can be distinguished from the circular shape if the effective diameter d' of the figure is equal to or greater than the resolving power δ_R by a factor d'/δ_R .⁹⁰

(Fig. 5⁹⁰) illustrates this criterion for a particle with n equal edges in the plane of the specimen. The criterion is expressed as a function of the ratio d'/δ_R , where d' is the effective diameter of the particle (circle of area equal to that of the n -sided figure). From an inspection of one of their micrographs (Fig. 6⁹⁰) it is shown that a hexagonal particle of diameter $d' = 40$ millimicrons can be recognized with a resolving power $\delta_R = 8$ -10 millimicrons. The hexagonal structure is recognized with a

d'/δ_R ratio between 4 and 5. The necessary value, according to the chart, is between 8 and 10, indicating that the criterion in this case is excessively stringent. The necessity for such a criterion is obvious. The above numerical comparison, however, indicates a further necessity for the specification of the conditions under which the particles are observed.

It is suggested by the writer that a measurement of the chords of the rounded corners of particles of known simple geometry might be used as a measure of the practical resolving power. Such linear measurements, independent of "just perceptible" contrast differences, in the micrographs of easily reproducible test specimens (*e.g.*, the freely supported magnesium oxide smoke particles²⁸), would eliminate, further, the variables introduced by a supporting film and the dimensions and densities of neighboring "point" scattering centers which have been used as test objects in the past.

FIGURE 16a. Stereoscopic electron micrographs of a mosquito larva trachea. (Courtesy *Science News Letter*).¹³²

Since the focal depth of the electron microscope is very large, it is possible to measure directly in a micrograph only the two dimensions of a structure which are parallel to the plane of the specimen. In the study of larger structures (dimensions in excess of *ca.* $\frac{1}{10}$ micron), or of large aggregates of small particles, stereoscopic projections provide instructive pictures which reveal the three-dimensional geometry. The method is of great value in demonstrating the architecture of such structures as diatoms,^{21b} and skeletal sections of insect morphology, examples of which are shown in Fig. 16.^{1, 132} It also provides useful information regarding the state of aggregation of crystallites.

The value of this method for the numerical determination of the third dimensions of small colloidal particles, however, has not been proven. The success in obtaining stereoscopic projection depends critically upon the degree of accuracy with which the component micrographs can be superimposed. Slight variations in the relative disposition of the specimen particles resulting from altered conditions of illumination, as well as slight errors in the relative magnifications or orientation of the micrographs, have a serious effect on stereoscopic projection. The inherent inaccuracy of small measurements by parallax methods may be greatly enhanced by faulty projections.

One example of the inconclusive results which have been obtained by application of this method is provided in the publications of Schoon and Koch¹⁴⁹ and of Heering, Gizycki and Kirseck.⁷³ The former concluded that commercial colloidal carbon consisted of platelets of circular or elliptical shape. In the later publication of Heering *et al.*, it is concluded that the shapes are spheroidal. The thickness determinations of thin crystal plates of clay minerals by this method, as reported by Eitel and Gott-

FIGURE 16b. Stereoscopic views of fractured non-iridescent wing scale of *Morpho Cypris* showing nature of supporting rods. 12° stereoscopic angle.¹

hardt,⁵⁸ cannot be regarded as significant for yet an additional reason. The third dimension, or thickness, of the plates measured by these writers is evidently below the resolving power of the instrument. Consequently, even a direct measurement of the plate thickness would be impossible.

At the present time there appears to be only one possible direct method for the accurate determination of the third dimension. It is the simple procedure of rotating the specimen through large angles about an axis perpendicular to the optic axis of the instrument and procuring micrographs at angles of orientation for which selected particles reveal their *minimum* dimensions. Since particles tend to be oriented with

their flat sides parallel to a supporting film, this type of specimen support is unsuitable. The preferred orientation may be reduced through the use of a fine plastic screen in place of a film.

This direct method is inapplicable in the measurement of extended plates or films, the thickness of which is comparable with or below the resolving power of the instrument. In this range, the only apparent possible method at present is the indirect method of interpreting the image intensity, as described by Marton and Schiff.¹¹⁶

Studies of Clay Minerals.* Aside from the practical importance of clay minerals in soils, construction engineering, the ceramic, rubber, paper, petroleum, metal-founding and other industries, the complex structures of these hydrous aluminum silicates are of considerable interest from an academic viewpoint. Due to the efforts of research workers in many fields, a vast amount of information has been accumulated

FIGURE 17. The crystal structure of the clay minerals. (a) Arrangement of atoms in the sheets; (b) arrangement of atoms in a single crystal plate; (c) in the models of kaolinite (left), montmorillonite (center) and the expanded lattice of montmorillonite (right).⁸¹

regarding the physical, chemical and crystalline properties of these materials. Grim⁶⁹ has thoroughly reviewed the significant findings regarding clay prior to the advent of the electron microscope, and for a full discussion, the reader is referred to his excellent paper.

According to Grim, "Two structural units are involved in the atomic lattices of the clay minerals. One is the alumina or aluminum hydroxide unit, which consists of two sheets of closely packed oxygens or hydroxyls between which aluminum atoms are embedded in such a position that they are equidistant from six oxygens or hydroxyls. Actually, only two-thirds of the possible aluminum positions are occupied in this unit, which is the gibbsite structure. The mineral brucite possesses a similar structure except that all possible aluminum positions are occupied by magnesium. The second unit consists of a sheet of tetrahedral silica (SiO_4) groups linked to form a hexagonal network of the composition Si_4O_{10} when repeated indefinitely. This unit

* A number of papers in earlier volumes of this series deal with various aspects of clays, *c.g.*, in Vol. III, by K. von Terzaghi, J. di Gleria, and Fr. Zuker, R. Bradfield. J. A.

may be viewed as a sheet of loosely packed oxygen atoms with each oxygen linked to two silicon atoms directly beneath. The silicon atoms are in tetrahedral positions, three valences being satisfied by linkage to three oxygens in the overlying sheet. The fourth silicon valency is satisfied below by an oxygen atom such that this silicon valency is analogous to the common hydroxyl group of gibbsite."

Marshall¹⁰⁹ classified the known clay minerals into two main lattice types. The 2:1 type is composed of an alumina unit bound between two silica units, while the 1:1 type consists of a combination of one alumina unit and one silica unit. The two lattice types are illustrated in Fig. 17. A single plate of kaolinite is shown at the left, and a single plate of montmorillonite at the right. In the third illustration of Fig. 17 two plates of montmorillonite are separated by an intervening space in which it is believed adsorbed cations are held. The spacing between plates varies with water content, as shown by Hofmann, Endell and Wilm.⁸⁵

The properties of the 1:1 clay minerals—kaolinite, dickite, nacrite, and halloysite ($\text{Al}_2\text{O}_3 \cdot 2 \text{SiO}_2 \cdot 2 \text{H}_2\text{O}$)—are closely similar.¹⁰⁹ The unit plates of the 1:1 minerals are more firmly bound together than is the case with most 2:1 minerals, probably because of the attraction between O and (OH) layers which are adjacent.⁶⁹ These kaolin minerals exhibit only slight hydration and adsorptive properties. Base-exchange capacities are of the order of 3 to 15 milliequivalents per 100 g.

All 2:1 clay minerals are considered to have similar structural features, the 2:1 layer lattice of Hofmann, Endell and Wilm representing the type form. Marshall¹⁰⁹ and others treat the various minerals in this group as an isomorphous series. Certain replacements in the lattice are supposed to operate, *viz.*, aluminum replacing silicon in silica layers, as in the micas and feldspars, and magnesium replacing aluminum in alumina layers. Iron also replaces aluminum in the alumina layer. In the absence of any replacements, we have the alumino-silicate, pyrophyllite, and the analogous magnesium silicate, talc. These minerals do not exhibit variable spacings between unit plates and their base-exchange capacities are very low. In montmorillonite the chief replacement is magnesium for aluminum in octahedral coordination. This gives rise to a charged lattice, and exchangeable cations are necessary to balance the charge. In beidellite the chief replacement is aluminum for silicon in tetrahedral coordination. This replacement also requires exchangeable cations for balance. Ferric iron can be substituted for aluminum in octahedral coordination through the montmorillonite-beidellite series.⁷⁷ Possible end-members for these iron substitutions are nontronite and aluminum nontronite, which are essentially free of magnesium. Magnesium bentonite apparently owes its base-exchange capacity to a substitution of lithium for magnesium in octahedral coordination.⁷⁷

Before the advent of the electron microscope, the shape and dimensions of clay particles had been inferred from indirect evidence. Baver,³¹ in a discussion of shapes of clay particles in 1940 states, "This sheet-like structure of the crystal, which is similar to that of mica, would be expected to favor a plate-like shape of the entire particle, rather than a cubical, spherical or rod-like form." Grim⁶⁹ in 1941 stated, "At the present time there are few students of clays who would dispute the premises that clays are composed of flake-shaped particles." Hendricks'⁷⁷ estimates of particle dimensions are given in Table 1.

Table 1. Order of Particle Dimensions of the Silicate-Layer Minerals (in Centimeters)

| | | | |
|------------|---------------------|------------------|---------------------------------------|
| Anauxite | 10^{-1} | Antigorite | $10^{-5} - 10^{-6}$ |
| Nacrite | 10^{-1} | Micas | 1.0 |
| Dickite | $10^{-2} - 10^{-3}$ | Hydrous micas | $10^{-4} - 10^{-5}$ |
| Kaolinite | $10^{-4} - 10^{-5}$ | Pyrophyllite | $1 \times 10^{-1} - 1 \times 10^{-3}$ |
| Halloysite | 10^{-5} | Talc | $10 - 10^{-3}$ |
| Chrysotile | 10×10^{-7} | Montmorillonites | $10^{-5} - 10^{-6}$ |

Since most of the physical and chemical properties of clays are closely related to particle shapes and the extent and nature of surfaces exposed, it is very natural that

FIGURE 18a. Dickite crystal lying flat.

FIGURE 18b. Same dickite crystal standing approximately on edge.⁸⁷

FIGURE 19a. Kaolinite.

FIGURE 19b. Dickite.

clay scientists should be among the first to make practical use of the electron microscope. It was first used by the German investigators, Eitel and others^{58, 59, 60, 61} and by von Ardenne, Endell and Hofmann²⁵ in 1939 and 1940. B. T. Shaw and his students at Ohio State University began their studies^{86, 87, 93, 110, 151, 152} shortly afterward. The published work concerns two main objectives; (1) to characterize the various clay minerals by their appearance, and (2) to evaluate the extent and nature of the surface exposed by various size ranges of the several minerals.

The first *direct* evidence bearing on the plate-shaped nature of clay was provided by Humbert and Shaw⁸⁷ with successive exposures of the same crystal of dickite, first with the *c*-axis parallel to the optic axis of the instrument, Fig. 18a; and then with the *c*-axis approximately perpendicular to the optic axis, Fig. 18b. Since the crystal was vibrating during the second exposure it is not possible to give an accurate axial ratio. It is of the order of 10:1.

Three minerals of the 1:1 lattice type are shown in Fig. 19: (a) kaolinite,¹⁵¹ (b) dickite¹⁵² and (c) halloysite.¹⁵² These electron micrographs are characteristic

FIGURE 19c. Halloysite.^{150,152}

of a large number of observations of minerals from various sources. Kaolinite particles are seen to be composed of an orderly arrangement of thin, well-defined crystals. The 120° interfacial angle is evident. Shaw estimates the thickness of the thinnest crystals to be less than 5 μ . This would give axial ratios of the order of 100:1. The individual crystals of dickite show a much greater development along the *c*-axis than is the case with kaolinite. The axial ratios are of the order of 10:1 to 15:1.⁹³ The halloysite structure was quite surprising. Hendricks⁷⁷ stated in 1941, "There is no reason at the present time for considering halloysite ($\text{Al}_2\text{O}_3 \cdot 2 \text{SiO}_2 \cdot 2 \text{H}_2\text{O}$) to have types of layers different from kaolinite, nacrite and dickite. New evidence, however, might be found that would lead to a more complete understanding of its structure. The powder-diffraction pattern of halloysite differs somewhat from kaolinite, but in a manner that can be accounted for by its degree of organization." The marked differences in crystal habit of these three minerals is far greater than has been suspected on the basis of other evidence. They do have one feature in common. All show well-defined, sharp, straight-edged crystals.

Shaw¹⁵¹ made some interesting observations regarding the exchange capacity of kaolinite. The basic material for his study was unground kaolinite (Fig. 20a) having an exchange capacity of 3.8 me/100 g. Samples of this material were ground in a ball mill in the dry state and also as a thin paste in water. The sample wet-ground

for 144 hours (Fig. 20b) had an exchange capacity of 16.6 me/100 g. The sample ground 144 hours in an air dry state (Fig. 20c) had an exchange capacity of 49.5 me/100 g. "It is seen that the wet grinding caused the particles to separate along cleavage planes. Also there has been some breaking of crystals as is evidenced by

FIGURE 20a. $<0.5\mu$ Fraction of kaolinite (unground).

the absence of the well defined crystal edges shown in the unground material. There is little evidence of cleavage in the dry ground material. The relatively thick irregular fragments have obviously resulted from crystal fracture. The much greater increase in exchange capacity is fairly definite evidence that the exchange positions on kaolinite are located at plate edges."

FIGURE 20b. $<0.25\mu$ Fraction of kaolinite (wet-ground).

The existence of a difference in the adsorptive properties of cleavage and fractured surfaces was suggested as the cause of anomalies in the study of clay gel viscosities by Ford, Loomis and Fidium.⁶⁴ The observations of Shaw thus provide the first direct experimental evidence in this type of problem which is characteristic in the specification of the colloidal properties of a great many materials.

FIGURE 20c. $<0.25\mu$ Fraction of kaolinite (dry-ground).¹⁵¹

Four minerals of the 2:1 lattice type are shown in Fig. 21. These are: (a) montmorillonite from California;⁸⁷ (b) montmorillonite from Wyoming bentonite;¹⁵¹ (c) beidellite from Putnam Clay (100-50 $m\mu$, Equivalent Spherical Diameter, abbreviated to ESD in the following);¹¹⁰ (d) beidellite from Putnam clay ($< 20 m\mu$ ESD);¹¹⁰ (e) nontronite (200-50 $m\mu$ ESD);¹¹⁰ (f) nontronite ($< 50 m\mu$ ESD);¹¹⁰ (g) magnesium bentonite (500-200 $m\mu$ ESD);¹¹⁰ (h) magnesium bentonite ($< 50 m\mu$ ESD).¹¹⁰ If these four minerals belong to the same isomorphic series, as has been suggested, then the isomorphism is restricted to fine structures, indeed.

FIGURE 21a. California montmorillonite.

The crystal habit of montmorillonite is well shown in Fig. 21b. The larger particles are seen to be composed of extremely thin plates. Many of them exhibit a fair degree of orientation of plates. This material was fractionated by the double-layer technique of Marshall,¹⁰⁸ so that the sedimented particles should be in the size range from 2 to 1μ ESD. The fine plates evident in the micrograph were dispersed, in the gentle treatment of washing the material from the centrifuge tube, from the

larger particles characteristic of the settling velocity. This shows how loosely the unit plates of montmorillonite are bound together. The finest plates in the micrograph are very probably of unit thickness, ($1\text{ m}\mu$) as will be discussed later. Ultimate dispersion would separate all particles into plates of unit thickness. Axial ratios for the unit plates are of the order of 250:1. Aggregates of overlapping

FIGURE 21b. $2 - 1\mu$ Fraction of Wyoming bentonite.

FIGURE 21c. $100 - 50\text{ m}\mu$ Fraction of beidellite.

plates have an appearance similar to the particles of montmorillonite shown in Fig. 21a. This suggests that possibly the real difference between the two montmorillonites shown may be only one of plate area. The particles of the California montmorillonite appear to be relatively thick aggregates of small plates, whereas the particles

of Wyoming bentonite are composed of relatively large plates in parallel orientation. In either case the thickness of plates is probably of the same order of magnitude. The vast amount of exposed surface per unit weight of material is evident.

FIGURE 21d. <20 $m\mu$. Fraction of beidellite.

FIGURE 21e. 200 — 50 $m\mu$. Fraction of nontronite.

The beidellite shown in Figs. 21c and 21d, is also plate-shaped. In this particular clay there is no evidence that particles of smaller settling velocity are produced by micaceous cleavage alone from those of larger size. Neither do particles in the fraction 100-50 $m\mu$ show a composite character such as might be expected if they were built up from units in the 20-5 $m\mu$ range.¹¹⁰ The substitution of aluminum for silicon in the crystal lattice has not created sufficient strain to inhibit the indefinite extension of the crystal in two directions so that beidellite is plate-shaped. The crystal plates are more firmly bound together in beidellite than they are in montmorillonite. This substantiates the views of Marshall.¹⁰⁹

The nontronite shown in Figs. 21e and f has the shape of thin blades or laths. Evidently the substitution of ferric iron for aluminum distorts the lattice to limit

FIGURE 21f. <50 m μ . Fraction of nontronite.

FIGURE 21g. 500 – 200 m μ . Fraction of magnesium bentonite.

the width of crystals. This same phenomenon has been observed⁷⁷ when magnesium replaces aluminum in the kaolinite structure, thereby giving rise to chrysotile asbestos, Fig. 22. It is also shown when magnesium replaces aluminum in the montmorillonite structure, giving rise to magnesium bentonite, Figs. 21g and h. The magnesium substitution appears to give rise to a greater distortion than the iron substitution, since the crystal widths are much more limited in the case of magnesium.

The use of the electron microscope has thrown considerable light on the meaning of the mechanical analysis of clays. Kelley and Shaw⁹⁸ have studied sedimentation

analyses in relation to particle shapes. They found that a particle size distribution of many clays, notably montmorillonite, merely reflects the degree of dispersion. This is well shown in Fig. 23: (a) Wyoming bentonite ($2-1\mu$ ESD); (b) Wyoming bentonite ($0.5-0.2\mu$ ESD); (c) Wyoming bentonite ($< 50 m\mu$ ESD). These fractions were prepared from the same material as that shown in Fig. 21b, and in the same manner, except that the fractions shown in Fig. 23 were redispersed and re-settled four times to assure sharp boundaries. A comparison of the four micrographs justifies the conclusion that the larger particles of this montmorillonite are aggregates of the thin crystal plates shown in Fig. 23c. By making use of the electron microscope it was possible to measure two of the dimensions of the particles. The third dimension could then be calculated from settling velocity considerations. In the case of the smallest fraction of montmorillonite, shown in Fig. 23c, the lower limit of settling velocity is not defined, so it is not possible to make mean thickness calculations. If one assigns the settling velocity of the upper limit to particles of greatest area, an estimate of maximum thickness of these particles can be made.

FIGURE 21h. $< 50 m\mu$ Fraction of magnesium bentonite.^{151, 152, 110}

FIGURE 22. Chrysotile asbestos.¹¹⁰

Such a calculation gives an average maximum thickness of 1.9×10^{-7} cm for ten of the larger particles.¹⁵¹ A unit plate of montmorillonite is about 1.0×10^{-7} cm thick. It is highly probable that this fraction is composed largely of crystals of unit thickness. Shaw¹⁵¹ explains many of the properties of montmorillonite that had been attributed to an expanding lattice as a consequence of the fact that an ultimate dispersion of this material results in plates of unit thickness.

FIGURE 23a. 2 — 1 μ . Fraction of Wyoming bentonite.

FIGURE 23b. 0.5 — 0.2 μ . Fraction of Wyoming bentonite.

A summary of Kelley and Shaw's studies with plate-shaped particles is given in Table 2. Their studies of halloysite, a rod-shaped mineral shown in Fig 19c, led them to the conclusion that the fractionation of rod-shaped particles on the basis of settling velocity is not accomplished with the same degree of accuracy as can be obtained with plate-shaped particles. The fact that particles of the same size occur in all fractions is shown in Table 3.

FIGURE 23c. <50 m μ Fraction of Wyoming bentonite.¹⁵¹

The lack of fractionation of fibers on the basis of settling velocity is also shown by the work of Marshall and others¹¹⁰ with the mineral attapulgite. The fraction 200-50 m μ ESD is shown in Fig. 24a and the fraction < 50 m μ ESD is shown in Fig. 24b. The cubical mineral grains are impurities in the attapulgite. It is evident that the impurity has been fractionated, whereas the dimensions of the attapulgite fibers are fairly constant for the two fractions.

FIGURE 24a. 200 - 50 m μ Fraction of attapulgite.

The study of clays with the electron microscope has barely begun. Research in progress on the perplexing problem of aggregation in soils promises to be fully as enlightening as any studies so far completed. Considerable information is being gained regarding the changes that take place in clays subjected to such standard treatments as grinding, heating, electrodialysis, oxidation and reduction.

Studies of Colloidal Carbon. A comprehensive review of the significant properties of a material of great industrial importance, colloidal carbon, is contained in a publication of the Columbian Carbon Company Research Laboratories.⁵⁴ "Over two years ago, in Volume II of this series, the size and shape of the ultimate particles of carbon black (Micronex) were determined by the aid of the electron microscope. The surface area was shown to be more than double that previously assigned. Particle shape as an explanation for carbon differences was eliminated. This marked a major turning point in the theory and practice of reinforcement.

"With this new and refined instrument it is now possible to attempt the quantitative evaluation of surface area as a clue to rubber compounding and other chemical and physical properties. In the following studies the carbon spectrum is analyzed from this point of view. Surface area is shown to be the dominating influence, subject, however, to important and sometimes controlling anomalies. These are shown to be largely resolved on the assumption that carbon structure, in addition to surface area, plays an important role.

FIGURE 24b. <50 m μ . Fraction of attapulgite.¹¹⁰

"During the past six months the above methods of analysis have been applied to the study of carbon reinforcement in synthetic rubbers. The role played by surface area has been found to be even more essential than in the case of natural rubber. The importance of carbon structure has likewise been confirmed.

"It is hoped that this new approach may serve a useful purpose, not only in the development of a general theory of reinforcement, but also in the most effective application of colloidal carbons to synthetic rubber compounding, now perhaps Research Problem No. 1 in this country."⁵⁴

An interesting feature of the investigations reported in this brochure is the comparison of the particle-size determinations by several of the established indirect methods with the direct measurements in electron micrographs. This comparison is summarized in Table 4, in which the numerical values are the results of independent investigations extending over a period of several years. Exact references to these are included in the above publication.

The appearance of two of the more commonly used carbons is illustrated in Figs. 25 and 26 (Figs. 14, 16, and 8⁵⁴). Although the spheroidal shape of the particles cannot be established directly from the observations in these micrographs alone, the assumption is probably justified on the evidence that particles showing marked dissymmetry are not to be found in any of numerous micrographs of specimens prepared by different procedures. If plate-shaped particles predominated, there should be an appreciable probability of finding some of these oriented otherwise than parallel to the specimen plane, especially about the aggregates evident in the micrographs.

In accordance with the criterion illustrated in Fig. 15, crystal habit of the carbon particles should be recognizable in the micrograph of Micronex, Fig. 25a, if the number of corners or straight edges in the images of the particles is less than 6 (mean particle diameter $d' = 28$ m μ , estimated $\delta_R = 5$ m μ , $d'/\delta_R = 5-6$). The experimental test of this criterion, discussed in Section VI(a), paragraph 2, indicates that crystal habit should be recognized if the number of straight edges is

less than 10 – 12. On this basis, it may be inferred that the greater proportion of the Micronex particles have more than 10 – 12 edges in the plane of the specimen, and therefore a poorly developed crystal habit. A similar and more definite conclusion may be drawn regarding the crystal development of the greater proportion of the particles of P-33, Fig. 26.

A second illustrative feature in these micrographs is the demonstration of the effect of specimen thickness on the resolving power exhibited in the micrographs [ref., paragraph 1 of Section V and Section III(c)]. With a particle thickness of 28 mμ and a beam potential of 44 kv, the existence of individual particles in clusters of small numbers is clearly revealed by the resolution of overlapping boundaries. In the micrograph of the larger particles, Fig. 26, taken with a beam potential of 54 kv, the complete contours of individual particles in clusters is entirely obscured.

(a) Analysis by ⁵⁴ of the distribution curves of Schoon and Koch ¹⁴⁹ who assumed that the particles were plate-shaped.

(b) Measurement of the diameters of a few particles in the micrographs of Heering, *et al.*⁷³ by ⁵⁴

(c) Determined from distribution curves of large numbers of particles in each carbon by the Columbian Carbon Company Research Laboratories.⁵⁴

The second micrograph of Micronex, Fig. 25b, is reproduced here for the purpose of illustrating the effect on image definition of the method of supporting the particles. The specimen of Fig. 25a was prepared by dispersing a sample over the surface of a uniform cellulose nitrate film. The specimen of Fig. 25b was dispersed in a cellulose nitrate solution which was subsequently cast into a film. The reduced contrast and resolving power may be ascribed to the enveloping film about the particles.

The relationship of carbon surface area to the macroscopic properties of suspensions is made evident in the charts, illustrated in this brochure. The electron microscope studies have provided the first definite evidence of a difference in the properties of colloidal carbons of equal surface areas but prepared under different conditions. Whether or not it will be possible to trace these differences by means of the electron

FIGURE 25a. Dry Micronex carbon dispersed on a film.

microscope cannot be predicted. That differentiation of surface properties in terms of crystal faces is possible is illustrated by the observations of Shaw.¹⁵¹ The "structure" differences appearing in the carbons may be of two kinds, *viz.*, (a) the occurrence in suspensions of complexes composed of ultimate particle or particle-molecular aggregates; (b) individual carbon particles, composed of aggregates of small graphitic layers³⁵ may have states of organization wherein certain crystal faces are exposed in varying degree.

Photographic Emulsions. An interesting example which might be included in this section to illustrate the discovery of entirely unexpected particle shapes, is provided by the studies of photographic emulsions which have been carried out in the Research Laboratories of the Eastman Kodak Company. In a preliminary publication by Hall and Schoen,⁷² it is shown that developed silver bromide crystals are not 'coke-like' structures as previously had been inferred, but consist of a mass of angled filaments. Lippman emulsions, containing the smallest photographic crystals, demonstrate this very clearly. Undeveloped silver bromide crystals are shown in Fig. 27a. When developed in common chemical developers, each small crystal grows into a single filament which is much longer and thinner than the original

crystal. The resulting worm-like structure of a developed Lippman emulsion is shown in Fig. 27b.

Cellulose Fibers. Electron microscope investigations which have been reported concerning the structure of textile fibers have had as their primary objective the exploration of the utility of the instrument in this field. In view of the several theories which have been postulated regarding the organization of the primary-valence molecular chains of cellulose into microscopic fibers, it is of some interest to review the published electron microscope observations.

FIGURE 25b. Micronex carbon dispersed in cellulose nitrate solution. Mean particle diameter, 28 m μ . (Magnification 50,000 diameters).⁵⁴ (Courtesy Columbian Carbon Co.)

In the earliest publication, by Ruska,¹³⁸ micrographs of *cut sections* of a variety of textile fibers are illustrated. Ruska presupposed that crystalline micelles could be revealed in the micrographs of transverse sections, and would appear as a system of adjacent particles of circular cross-section with interspaces bounded by convex surfaces. His failure to observe such configurations in micrographs of specimens of *ca.* 1 micron thickness led him to unjustified conclusions. In his micrographs, the marrow of a cotton fiber appears as a network with a system of holes bounded by concave surfaces. Both the shapes of these holes and their dimensions (of the order of 1 micron in diameter) are regarded by Ruska as evidence to vitiate the existence of crystalline micelles as significant structural units. The conclusions drawn from these micrographs are not considered to be beyond question. Cut sec-

tions of organic materials of the thickness studied by Ruska are likely to suffer appreciable structural changes as a result of electron energy absorption. The observations of Barnes and Burton²⁹ verify this statement. This could completely obliterate the natural structure in the interior of such a specimen.

In a second publication, Ruska and Kretschmer¹⁴⁰ reported the observation of the products of degradation from cotton fibers treated with hydrochloric acid and cuprammonium. Electron microscope specimens were prepared by three procedures,

FIGURE 26. P-33 Carbon. Mean particle diameter, 74 μ . (Magnification 50,000 diameters).⁵⁴ (Courtesy Columbian Carbon Co.)

viz., (a) centrifuging samples treated with HCl for various periods, dispersing the sediment in distilled water and drying the suspension on a specimen holder; (b) neutralizing the HCl, dialyzing the solution, and drying the products on a specimen holder; and (c) drying a dilute HCl suspension on a specimen holder. The specimens prepared by the procedures (b) and (c) exhibited a fine structure resembling a spongy film or the marrow of the untreated sectioned fibers. More clearly defined fibrous structures were observed in the specimens which had been centrifuged. In these specimens, the characteristic structures consisted of long fibers, each between 10 and 100 millimicrons in width and between 0.5 and 1 micron in length. Particularly interesting were the fibers revealed after a nineteen-hour acid treatment. These showed a width of *ca.* 5 millimicrons, corresponding to the x-ray measure-

ments of the cross-section of the cellulose crystallite. Ruska and Kretschmer express the opinion, however, that the source of these fibers is in the bark of the microscopic fibers.

The investigations of Sears and Kregel¹⁵⁰ on fine fractions of paper making fibers reveal the prominent existence of fine fibrous components. "The most interesting observation up to this time is the existence of fine fibrils in the fibers and fiber fragments of all stocks that have been examined."¹⁵⁰ Although the dimensions of these fibers, as reported by Sears and Kregel, do not indicate that fibers of the cross-sectional dimensions of crystallites are isolated, this investigation does contradict the conclusion of Ruska that the origin of the fine fibers is in the bark or skin substance alone.

FIGURE 27. (a) (left) Undeveloped silver bromide crystals from Lippman emulsion; (b) (right) crystals developed in a common chemical developer.⁷² (Courtesy Eastman Kodak Co., Rochester, N.Y.)

Barnes and Burton³⁰ examined specimens of both growing and mature cotton fibers disintegrated by mechanical shredding. Although two types of structures are revealed in their micrographs, *vis.*, very long fibers and a few rectangular-shaped particles, the greater proportion of the disintegrated material is fibrous in character. A micrograph of 15-day old cotton fibers is reproduced in Fig. 28. Structures in similar specimens of mature fibers are sufficiently similar to be indistinguishable from those observed in the specimen of growing fiber.

Inspection of the finer fibers revealed in all of the micrographs which have been published shows that the widths of the fibers vary continuously from below *ca.* 5 millimicrons up to several microns. Clear evidence of the existence of an *ultimate unit* fiber width is lacking. A number of fibers may be found in these micrographs which have a tapered shape, with the width of the marrow ends approaching the limit of resolution of the electron microscope. If the finer fibers consisted of crystallites, 60 millimicrons in length and cemented together end-to-end with a pectinous material, some periodic irregularity in the apparent width or density of the

fibers should be observable. Absence of observable density variations along the length of the smallest fibers, together with the continuous range of widths of the disintegrated fibers, might be considered as data compatible with the model of fiber structure postulated by Hengstenberg and Mark.¹⁰⁷

The occurrence of a relatively small proportion of material in the form of rec-

FIGURE 28. Fifteen-day cotton fiber (X 8000) partially disintegrated. Two phases can be seen—a very dense material which is almost completely opaque to electrons, and an extremely fibrous material.³⁰ (Courtesy American Cyanamid Co.)

tangular particles, such as those shown in Fig. 28 is of some interest. Although the dimensions of these particles are comparable with the structural units postulated by Farr and Eckerson,^{63, 62} common identity does not appear justified because of their relatively small number. Other types of particles have been observed by Barnes and Burton, however, in the material leached out of the surface of 15-day cotton fibers. The dimensions of these particles are more nearly compatible with the elliptical units observed by Farr under the light microscope.

Surface Studies. The direct examination of the surface features of specimens by means of reflected electrons has met with little success. As a result of the large velocity distribution in a reflected beam, the resolving power is greatly reduced.

Ruska and Müller¹³⁵ investigated the possibilities of this method by mounting a

specimen with its plane tilted about 5° from the perpendicular to the optic axis of the instrument and illuminating it with a beam at 90° to this axis. The low resolving power and low image intensity obtained in this way limits the useful magnification of the image to that which can be obtained with a low resolving power light microscope. Other advantages of using the electron microscope for this purpose are not apparent.

Somewhat greater resolving power and considerably more image intensity are gained in the procedure of von Borries.⁴⁰ The surface plane of the specimen is nearly parallel to the optic axis and is illuminated with an electron beam at grazing incidence. The resulting image distortion, however, makes the method impractical.

"An image, no matter how produced, may be regarded as subdivided into individual image elements, each of which bears a certain definite relationship to an elementary area of a similarly subdivided object. If the geometrical arrangement of the corresponding elements in image and object is similar and if there is a regular relationship between certain characteristics of the image elements, for example, brightness or color, and the same or other characteristics of the object elements, such as transparency, reflectivity, or mass density, the image is regarded as faithful.

"The formation of an image may result either from the simultaneous imaging of all the elements, as in the projection of a picture on a screen, a photographic plate, or retina of the human eye by optical lenses, or by the successive recording of individual image elements, a process familiar today from the practice of television."¹⁶¹

von Ardenne^{4, 6} was the first to attempt the exploitation of the principles in the above statement to overcome the limiting effects of chromatic aberration on the resolving power in the examination of thick specimens. In his scanning microscope, the specimen was placed in the principal focal plane of a strong magnetic lens which served as the second stage in the reduction of an electron source to a fine probe. Such a probe, incident on a specimen at any point, is scattered or absorbed in accordance with the discussion in Section III (a). By placing an aperture-limiting diaphragm between the specimen and the sensitive surface of a recording mechanism, the number of electrons reaching an image element is equal to the number which would pass through the objective lens of a transmission microscope as illustrated in Fig. 8. Thus the contrast in the images of this scanning microscope is determined by the factors governing the contrast in transmission microscope images obtained with an objective lens provided with an aperture-limiting diaphragm. Since the intensity is governed by the number of transmitted electrons, independent of their velocities, the effect of chromatic aberration in the final image is entirely eliminated. By placing a thin membrane between the final reducing lens and the specimen, which is sufficiently strong to serve as a vacuum seal, and yet transparent to an electron beam, von Ardenne considered it possible to attain a high resolving power in the examination of specimens mounted outside the vacuum chamber.

One successful method of recording the scanning microscope images provided by transmitted electrons involved placing a photographic film or paper immediately behind the specimen. The image of a small area of the specimen is recorded by displacing the photographic film in synchronism with the motion of the probe. In testing this apparatus with the type of specimen normally studied in the transmission microscope, von Ardenne concluded that a resolving power equal to the diameter of the scanning lines, *ca.*, 100 Å, was revealed in the direction of the scanning lines. In the perpendicular direction, the resolving power is limited by the distance between adjacent scanning lines. He did not succeed in demonstrating the usefulness of this apparatus for the study of the surface features of massive specimens. Although he recognized the possibility of using reflected or secondary electrons, the above described method of recording the images was inadequate.

The first successful microscope of this type, in which the resolving power of the metallurgical light microscope is exceeded, was described recently by Zworykin

Hillier and Snyder.¹⁶¹ The complex problems involved in the design of such an instrument, as well as the difficulties associated with the amplification of very small electron currents, are discussed in some detail in this paper. The principles of construction of this apparatus are illustrated in Fig. 29 (Fig. 9¹⁶¹). The electron probe is produced by forming a greatly reduced image of a normal electron source with the aid of the first two electrostatic lenses. An image of this probe is subsequently focused in the plane of the specimen at approximately unit magnification by means

FIGURE 29. Schematic cross-section of the scanning microscope of Zworykin, Hillier and Snyder¹⁶¹ developed for surface studies. (Courtesy RCA Laboratories)

of the third electrostatic lens. The use of this third relatively wide-aperture electron lens facilitates the insertion of a system of magnetic deflecting coils which control the motion of the electron probe over the surface of the specimen. The electron beam proceeding from the third lens passes through a weak decelerating lens to impinge upon the specimen. The decelerating lens serves the purpose of accelerating and guiding the slow secondary electrons emitted from the specimen to impinge upon a fluorescent screen without appreciably affecting the paths of the higher-speed electrons in the probe. Variations in secondary emission from different object elements become evident as variations in the light intensity emitted from the fluorescent screen. These light-intensity variations are subsequently amplified by means of a

photoelectric electron multiplier tube, ultimately to control the printing bar of a facsimile recorder providing the micrograph. The use of this photoelectric amplifying system provides a decided advantage in the detection of those secondary electron current variations which are of the same order of magnitude as the thermal noise in the input resistances of ordinary vacuum-tube amplifiers.

Fig. 30 (Fig. 13¹⁶¹) illustrates the appearance of the micrographs which have been obtained with this apparatus. The specimen in this case is the surface of a

FIGURE 30. Micrograph of a ground and etched surface of a specimen of Bakelite containing carbonyl iron particles obtained with the scanning microscope of Zworykin, Hillier and Synder.¹⁶¹ (Courtesy RCA Laboratories)

ground and etched surface of Bakelite containing carbonyl iron particles. The contrast in the image is due to variations in the secondary electron emission from different elements of the specimen. The contrast may be varied by using different electron probe accelerating potentials. Since the maximum sensitivity of secondary electron emission is in the neighborhood of several hundred volts, this scanning microscope is operated with lower beam accelerating potentials than are commonly used in transmission microscopes.

The intrinsic complexity of scanning apparatus relative to the simple lens system of the transmission microscope is a factor to be considered in evaluating the utility of the former type of apparatus in surface studies. It is apparent that results of greater immediate significance, particularly in metallographic problems, can be obtained through the study of *replicas* of surface features with the transmission microscope.

A number of methods for the preparation of replicas suitable for examination in

the transmission microscope have been described. The first, described by Mahl,¹⁰⁶ is applicable to the study of metals. It consists in preparing thin oxide films on the surface of metallographic specimens and removing these by chemical means. The success of this method depends upon the ease of oxidizing the metal and of subsequently removing the oxide film. Interpretation of the images of this type of replica is probably more difficult than in the case of the other types of replicas reviewed in the following.

FIGURE 31. Replica of Pearlite structure prepared by double replica process of Zworykin and Ramberg.¹⁶⁴ Opaque areas represent elevations; transparent areas represent depressions in original sample. Some of the rectangular opaque areas are probably undissolved silver or salt crystals.

In the more versatile procedure described by Zworykin and Ramberg¹⁶⁴ a relatively thick film of silver, evaporated from a heating element in a vacuum chamber, is condensed on the surface of the specimen. After removal of the specimen from the vacuum chamber, the silver film is stripped mechanically from the specimen, thus providing a "negative" replica. The thickness, and consequently the tensile strength, of this film can be made sufficiently great to obviate the occurrence of large-scale distortions in the stripping process. A dilute solution of cellulose nitrate, or other plastic, is subsequently spread on the surface of the silver replica to a depth which will dry to a film of sufficient transparency for examination in the electron microscope. Upon removal of the silver film with dilute acid, the cellulose nitrate film serves as a "positive" replica. In the ideal replica, the thicker areas appearing as dark areas in a micrograph represent elevations; the lighter areas represent depressions in the original specimen.

The applicability of this method is limited to those materials which can be placed in a vacuum chamber without suffering disintegration. In metallographic work, the

most serious restriction is imposed by the alloying of the evaporated metal with the original specimen. This may be overcome in many cases by selection of a more suitable metal for the negative replica. There is also some difficulty in dissolving the negative replica from the plastic "positive" with assurance that the metal is completely dissolved and that the structure of the "positive" has not been altered. The latter difficulty does not appear to be insurmountable. Presumably it may be avoided or eliminated entirely by choice of more suitable materials than silver and cellulose nitrate.

FIGURE 32. Replica of Pearlite structure prepared by initial single replica process of Schaeffer and Harker.¹⁴⁹ Opaque areas represent depressions; transparent areas represent elevations in original sample. The diffuse light lines are thought to represent strains in the replica. (Courtesy General Electric Co.)

The latter difficulty is, in fact, largely overcome in the double replica process developed by Heidenreich and Peck.^{75, 76} In their technique, a negative replica is placed in a vacuum chamber and has deposited on it a thin film of evaporated silica. The high mobility of silica during condensation is effective in the production of a silica film, one surface of which follows the contours of the negative, the other of which is plane within limits of practical interest. Such a silica film is more resistant to chemical action than is a plastic film. Consequently, a more faithful replica, insofar as cleanliness and maintenance of structure in the silica film are concerned, may be expected.

In the first step of the Heidenreich and Peck process, polystyrene is moulded on the surface of the specimen with high pressure and elevated temperature. The

moulded negative replica is then separated from the specimen by mechanical shock or by dissolving the specimen. The method is not applicable to the study of soft materials or of those materials which may be altered at the temperatures required for moulding. In the methods of both Zworykin and Ramberg, and Heidenreich and Peck, a vacuum evaporator is required and the preparation of a replica requires a considerable amount of time.

Several techniques have been devised by Schaeffer,^{141, 142, 143} for the preparation of negative replicas which may be examined directly in the electron microscope.

FIGURE 33. Replica of Pearlite structure prepared by double replica process of Heidenreich and Peck.⁷⁶ Opaque areas represent elevations; transparent areas represent depressions in original sample. (Courtesy Dow Chemical Co.)

The success in the preparation of sufficiently thin and strong replicas of this type depends in part upon the choice of replica material. Schaeffer and Harker discovered a satisfactory material, Formvar 15-95. Equally important to the success of the method is the observation of certain principles in the conditioning of the surface of the original specimen.

Schaeffer found that Formvar films of very small thickness, 100 Å or less, can be stripped easily from smooth surfaces, such as glass, if the glass is properly cleaned. "A single layer of molecules of a hydrophobic substance, such as grease or oil, will completely prevent carrying out this normal stripping process and it is necessary to increase the film thickness at least tenfold in order to add sufficient tensile strength to the film to enable its mechanical removal. Some evidence has been noted which indicates that conditioning metal surfaces with surface-active molecules such as tricresyl phosphate and oleic acid greatly facilitates the removal of replicas. Not more than a monolayer is needed for this purpose."

In order to obtain a coherent film from irregular surfaces, such as etched metallographic specimens, it is of course necessary to deposit films of average thickness considerable greater than 100 Å, for it is essential to have the thinnest areas sufficiently strong to permit stripping. From the results of experiment, Schaeffer and Harker estimate that an optimum compromise between adequate contrast and mechanical strength is obtained with average film thicknesses from 500 to 750 Å. Satisfactory replicas are obtained with the following procedure described by them.

"After the specimen has been given a good metallographic polish (we use MgO on polishing cloth known as kitten's ear for the final polishing of steel specimens), the surface is given an etch of such a depth that a fairly good photomicrograph can be obtained at 1000X in the light microscope. The etching solution is then removed and the surface quickly dried with a jet of clean filtered air. The specimen is then immediately lowered face down into a Petri dish containing a small amount of 0.5 per cent solution of polyvinyl formal dissolved in dioxane. The specimen is removed with a smooth motion and swung into a position such that the plane of the surface is vertical with respect to the surface of the resin solution. The solvent is allowed to evaporate to completion while held in the vertical position. This procedure forms a wedge-shaped film on the metal surface thickest at the lower edge and thinnest at the top. With a specimen having a diameter of 2.5 cm the range in thickness will be from 500 to 750 Å, although at the very bottom there will be a small area much thicker than this where the draining liquid accumulates."

The replica film may be removed from the specimen by several methods. The simplest technique, which at the same time avoids contamination of both the original specimen and the replica, is described in a recent article by Schaeffer.¹⁴² A standard specimen screen is placed over the region to be studied. "With the screen in place, a bit of moist air is applied to the coated surface and immediately a piece of scotch tape is pressed into light contact with the screen and the surrounding film. Holding the scotch tape against the specimen, on one side of the positioned screen, the tape is held rigidly and lifted away from the surface. When this is done the replica leaves the specimen and will be found in contact with the under surface of the screen ready for mounting in the specimen holders of the electron microscope. The scotch tape is easily removed from the mounting screen by placing the tape holding the screen in contact with a flat surface. The tape is then turned through 180°, and a finger placed on the sticky surface until the edge of the screen becomes visible. A razor blade or similar thin flat object held against the screen prevents it from becoming bent as the tape is peeled away from it. The entire process of replica formation, removal and mounting may be carried out in less than two minutes. Perhaps the most attractive feature of the process described is the fact that the specimen is not injured in any way. For example, from a specimen of 1.1 C Steel (used for developing the technique) at least fifty replicas have been obtained without injuring the surface in any way."

An evaluation of the relative merits of the above methods of preparing replicas in the study of materials for which any one of them may be applicable is difficult to carry out without making direct and detailed experimental comparisons. The most fundamental consideration in the value of a replica prepared by any of these methods is the faithfulness of the replica to the original surface. For a replica to be completely faithful, it should have one surface a precise counterpart of the original, while the other is plane. If both of these conditions are fulfilled, it is possible to use the thickness of the replica as a measure of the elevations or depressions in the original surface.

It is highly probable that the surface of an *evaporated* film adjacent to the original specimen is in intimate contact with it and consequently satisfies one requirement of an accurate replica. The degree to which it remains an accurate counterpart after removal depends upon the cohesive forces between the surface and the evaporated

film, and upon the magnitude of reentrant angles. It may be expected that in the stripping process, some portions of the negative remain embedded in the original, and in some cases, that some of the original features are pulled away with the negative.

A moulded replica may be in intimate contact with the original if it is sufficiently fluid during the moulding process. Accuracy of the replica in its finer details will also depend upon the relative magnitudes of surface tension in the plastic and of the cohesive forces between the plastic and the specimen surface. The amount of tearing of the plastic or of the original will depend upon the method used for separating them. Probably less rupturing occurs if the original is dissolved. The same factors must be considered if the negative replica is in the form of a solution when applied, as in the Schaeffer and Harker technique. In accordance with their test, it is apparent that an intimate contact is established between the resin film and the original, and it is thus permissible to regard the Formvar film as an accurate counterpart while it is in contact with the original.

On the basis of the above consideration, it is apparent that both the evaporated metal and the soluble plastic films are likely to be more accurate counterparts (in the finer details) than the moulded impressions. Of equal significance to the final result, however, is the effect on the replica of the method of separating the surfaces. The least alteration of the replica impression is likely to be incurred by dissolving the original specimen. Mechanical stripping will introduce distortions and ruptures to some extent. Large-scale distortions are likely to occur in stripping the thinner films of the Schaeffer and Harker technique. The existence of such distortions has been recognized by Schaeffer and Harker. Small-scale distortions due to cohesive forces, and reentrant angles are likely to occur in all the techniques. In the event of alloying, these effects are more serious in the Zworykin and Ramberg method.

The degree of flatness of the outer surface of the final replica is the second factor to be considered. In both the Formvar and silver collodion processes, it is assumed that the solutions spread on the irregular surface, will have a flat outer surface as a result of surface tension. The assumption has been partially verified by Schaeffer and Harker. It is evident, however, that the degree of flatness depends rather critically upon the depth of the film above the highest elevations in the irregular surface (in the original in the case of the single replica process; in the negative replica in the case of the double replica processes). A plane outer surface can only be assumed if the depth of the film is large in comparison to the depth of the highest projections (the case studied by Schaeffer and Harker). This probably is not the case if the films are made of a thickness to yield greatest contrast. In the polystyrene process, the high mobility of evaporated silica films was discovered by accident. Heidenreich and Peck express the opinion that the resultant film may be regarded as flat in the study of the finer details. Both surfaces of the silica film tend to follow the contours of the polystyrene surface. The outer surface, however, is considered to be smoother. The limits within which the outer surface may be regarded as flat have not been determined with any degree of accuracy.

It may be assumed that the film obtained by spreading a plastic solution over the irregular surface will result in a more faithful replica of the coarse features of the surface. In the single replica process of Schaeffer, the finer details are more likely to be revealed in the areas of the specimen representing elevations in the original surface. The films are thinnest in these areas and greatest resolution is obtained in the electron microscope images. On the other hand, the finer details in the depressions of the original surface are likely to be revealed in the double replica processes, since the thinnest film areas represent depressions. In those investigations in which finer details throughout the entire specimen are of primary interest, a silica film as a final replica will probably be most useful. The technique to be employed in any particular problem depends upon the nature of the material as well as upon the factors discussed above. Materials which are mechanically fragile, or sensitive to elevated

temperatures or abnormal pressures, are not capable of withstanding the treatment involved in the above double replica processes.

From inspection of the numerous micrographs which have been prepared through application of all of the above replica processes, it is evident that the highest resolving power exhibited in replica micrographs is lower than the optimum resolving power of the instruments. Although very sharply defined boundaries and particles frequently may be observed, it is not at all certain that these are true replica structures, for there is a strong probability that some of the finer structures of the original surface may be removed with a stripped replica. A reduced resolving power may be ascribed to one or both of two factors, *viz.*, insufficient image contrast to reveal the smaller thickness differences; failure of the replica to provide an accurate representation of the smaller structural units in the surface. It is apparent from the results obtained so far that crystallites of dimensions near the limit of resolution are not clearly revealed in the micrographs of replica specimens.

(b) **In Microbiology.** Exploitation of the electron microscope in the biological fields has been the objective of even the earliest workers engaged in the development of the instrument. The first micrographs of cell structures were obtained by Marton, in 1934,¹¹² who impregnated biological sections with osmium salts and so obtained images of the osmium skeletons which remained after the more sensitive cell materials had been destroyed by electron bombardment. Krause⁹⁸ later demonstrated that it was possible to study delicate cell structures without the use of dyeing or fixing agents. The results of these early investigations, however, were more significant in showing that the electron microscope was not particularly well adapted for the study of such massive structures as complete cells or cut biological sections. That the instrument was well suited for the study of the smaller biological structures represented by bacteria and viruses has been made clearly evident in numerous publications in which the appearance of many types of these organisms is illustrated.

FIGURE 34. Partially cytolized streptococcal cells under the action of sonic vibration.¹²² (Courtesy RCA Laboratories)

Bacterial Morphology. A number of instructive investigations in bacterial morphology have been reported. In publications of Mudd and Lackman,¹²² and of Mudd, Polevitsky, Anderson and Chambers,¹²³ evidence is presented to confirm the existence of a relatively rigid membrane enveloping the protoplasm of certain bacteria. The

most conclusive evidence is furnished by the micrograph Fig. 34 (Fig. 5¹²²) of streptococcal cells and Fig. 35 (Fig. 1¹²³) of *Bacillus megatharium* cells. In both cases, suspensions of the cells were partially cytolyzed under the action of sonic vibrations. Some of the cells among those in Fig. 34 have been cytolyzed and appear

FIGURE 35. Partially cytolyzed *Bacillus Megatharium* cells under the action of sonic vibration.¹²³

FIGURE 36. Intercellular plate of *Bacillus anthraxis*.¹²³

(Courtesy RCA Laboratories)

as "ghost" cells. These do not differ significantly in their outlines from the intact cells, but since they are much more transparent to the electron beam, it is evident that the protoplasm has escaped. In Fig. 35, there appear fragments of cells produced by sonic vibration. The undistorted tubular fragments with ragged ruptured ends again indicate the rigidity of the cell wall. Of further interest in this publication is the demonstration of the existence of the intercellular plate shown in Fig. 36 (Fig. 11¹²³). This evidently consists of a thickened area of cell membrane.

An exploratory investigation of the value of staining bacterial preparations with the object of revealing protoplasmic structure has been reported by Mudd and Anderson.¹²¹ Since the contrast in the electron microscope image is governed essentially by variations in the thickness-density of a specimen, characteristic internal structure is difficult to observe. Both the thickness and density of the organic compounds in

FIGURE 37. Enhancement of contrast by staining. (1) Unstained *Fusobacterium*; (2) stained with silver nitrate; (3) stained with mercury bichloride; (4) stained with lead acetate.¹²¹

the protoplasm are in general nearly uniform throughout. Some advantage might, therefore, be gained by the selective staining of cells with heavier elements, as initially suggested by Marton.¹¹² With these possibilities in mind, Mudd and Anderson prepared bacterial specimens stained with various heavy metals. It was found that the cell wall is unaffected by the stains, but that the stains are absorbed, as expected, by the protoplasm. Fig. 37 (Plate 11¹²¹) illustrates the absorption and increased contrast which results from the staining of specimens of *Fusobacterium* with silver nitrate, mercury bichloride and lead acetate. Although the selective action of these stains is not certain, the results do indicate that the development of this type of staining technique is a promising procedure in the study of protoplasmic structure.

The above demonstration, as well as the earlier investigations of von Borries, E.

Ruska and H. Ruska¹³⁶ concerning the identification of endo- and ectoplasm; the attempted demonstration of nucleic acid by Pickarski and Ruska;¹²⁸ and the study of tuberculosis bacilli by Lembke and Ruska¹⁰⁰ demonstrate the lack of sufficient "penetrating" power in this type of investigation with beam potentials below 100 kv. Greater progress in this phase of cell morphology will undoubtedly result through the use of higher-voltage instruments.

Several species of animal virus, in many respects closely related to bacteria, have also been demonstrated. The most instructive is the observation of morphological structure in vaccinia virus by Green, Anderson and Smadel.⁶⁸ It was found that the vaccinia virus particles have a rectangular shape in electron microscope specimens. An internal structure is revealed even with the use of a relatively low beam potential (78 kv). Elementary bodies of purified virus particles are shown in Fig. 38

FIGURE 38. Elementary bodies of purified vaccinia virus. Rectangular-shaped virus particles include dark spots revealing internal structure.⁶⁸

(Fig. 1a⁶⁸). The dark areas within the rectangular boundaries represent the internal structure, which is not yet explained.

Bacterial Reactions. A variety of bacterial reactions have also been demonstrated with the electron microscope. An interesting example is the study carried out by Ruska¹³⁹ in which he recorded the process of lysis resulting from the addition of phage to a suspension of colon bacteria. This is illustrated in the series of micrographs, Fig. 39, reproduced from his paper. The initial rapid absorption of the phage on the bacterial membrane is shown in upper left. The subsequent disintegration of the membrane, escape of the protoplasm and final destruction of the bacillus is demonstrated in the remainder of the series. It is perhaps unnecessary to point out that four different bacilli are involved in the series of micrographs.

It is evident that the phage particles, or bacterial viruses, shown in the above series have suffered structural alteration from the effects of electron bombardment. This is clearly revealed in an analysis of the forms of different strains of bacteriophage by Luria and Anderson.¹⁰² In the latter investigation it is shown, for example, that several species of colon bacteriophage consist of sperm-shaped particles.

A study of the alterations of the flagella and cell walls which result from specific

sensitization with anti-sera has been reported by Mudd and Anderson.¹²⁰ Figs. 40 and 41 (Figs. 3 and 4¹²⁰) demonstrate their observations. The flagella and the sharply defined cell walls exposed by shrinkage of the protoplasm *in the control specimen* are shown in Fig. 40. Fig. 41 illustrates that the antibodies of the serum have been adsorbed on the flagella. The presence of adsorbed material on the cell walls is indicated by their greater opacity to the electron beam. The relatively uniform increase in thickness of the flagella and the decrease in sharpness of

FIGURE 39. Lysis of colon bacteria by phage.¹³⁹ The structure of the phage particles, appearing as small annular particles, has been altered by electron bombardment.

FIGURE 40. *Eberthella typhosa* with heterologous anti-streptococcal serum.

outline have been explained by Mudd and Anderson on the assumption that the antibodies are rod-shaped, and are adsorbed on the surface of the flagella end-on, in a thickness of 21 Å.

Biochemical reactions may be studied with equal success. An interesting aspect of this problem is the determination of the locality of the chemical reactions which are brought about by bacteria. In a study carried out by Morton and Anderson¹¹⁹ diphtheria bacilli were grown in a chocolate agar containing potassium tellurite. In

FIGURE 41. *Eberthella typhosa* with homologous anti-typhoid serum.¹²⁰

FIGURE 42. Reduction of potassium tellurite to metallic tellurium by diphtheria bacilli; (a) (left) bacilli grown in chocolate agar containing potassium tellurite; (b) (right) bacilli grown in control agar of horse blood.¹¹⁹

the presence of these bacteria, the tellurium salt is reduced to metallic tellurium. Electron micrographs have revealed that the reduction takes place in the interior of the organisms and may be regarded as part of the digestion process of the cells. This is demonstrated in Fig. 42. The long needle-shaped crystals visible within the cells

shown in (a), are the product of the reduction of the potassium tellurite. The typical polar granules of the normal cells are shown in the comparison micrograph (b).

Protein Molecules. Several publications have appeared in which the appearance of isolated globular and crystalline protein molecules have been demonstrated. It has been the purpose of these investigations to obtain a correlation between the dimensions of the molecules computed from sedimentation and diffusion experiments with the dimensions of the particles observed in electron microscope specimens. The first

FIGURE 43. Single molecules of tobacco mosaic virus.¹⁵⁴ (Courtesy RCA Laboratories)

exploration of this kind was made by Kausche, Pfankuch, and Ruska,⁹¹ who examined specimens of tobacco mosaic virus suspensions. They demonstrated the existence of rod-shaped particles in specimens of TM virus, the measured dimensions of which were in satisfactory agreement with the accepted values. A further study of the size and shapes of these molecules was carried out by Stanley and Anderson.¹⁵⁴ From direct measurements in the micrographs of TM virus suspensions, one of which is illustrated in Fig. 43, Stanley and Anderson deduced a mean width of 15 mμ and a mean length of 280 mμ for the dimensions of these molecules.

The precise agreement of the direct measurements of the smaller dimension with the cross-section dimensions determined from x-ray measurements is somewhat misleading. The investigators have measured the widths of the particles in the image between boundaries which are not clearly defined. In view of the image contour phenomena discussed in Section III(b), and because of the lack of a sufficiently detailed knowledge of the scattering of electrons by structures of such small dimensions, the writer regards the implied magnitude of the probable error in these measurements as too small.

In a later publication of Stanley and Anderson,¹⁵⁵ the dimensions of individual particles of several more proteins are correlated with indirect measurements. Three of these are illustrated in Fig. 44 (Figs. 4, 5, 6, ¹⁵⁵). In the upper micrograph, of *Busycon canaliculatum* hemocyanin, the average diameter of 75 particles was found to be ca. 22 mμ, the majority of the particles having diameters between 19 and 24 mμ. An analysis of the suspension from which the specimen was prepared in the analytical centrifuge revealed the existence of three components, in the proportions 40, 20,

FIGURE 44. Protein molecules. Upper: *Busycon canaliculatum* hemocyanin with directly measured average particle diameter 22 mμ; center: *Limulus polyphemus* hemocyanin with directly measured average particle diameter 20 mμ; lower: *Viviparus malcatus* hemocyanin with directly measured average diameter 29 mμ.

and 40 per cent. Assuming that these molecules are spherical, the diameters computed from the sedimentation constants of these components are 10 μ , 19 μ , and 24 μ , respectively. It is evident from the value of the average of the directly measured diameters that the particles in the smallest size component are not revealed in the electron micrograph. Stanley and Anderson regard this as evidence to indicate that the molecules have the shape of prolate ellipsoids. This hypothesis is also indicated by the apparent thinness of the particles, judged by their relative transparency in the micrographs.

Somewhat similar conclusions were drawn from the electron micrographs of *Limulus polyphemus* hemocyanin, shown in the center of Fig. 44 (Fig. 5¹³⁵). The average diameter of 33 particles shown in this micrograph was found to be *ca.* 20 μ . Analysis of the suspension from which the specimen was prepared indicated that there were two components. On the basis of spherical particles, the diameters of the particles comprising the greater proportion of the material, *i.e.* 90 per cent, have a computed value of 19 μ . The greater opacity of the particles appearing in the micrograph, as well as the close agreement of the computed and directly measured diameters, led Stanley and Anderson to the conclusion that the particles in the specimen are spherical in shape.

In the case of the particles of *Viviparus maleatus* hemocyanin, shown in the lower micrograph of Fig. 44, about 32 particles have measured diameters of 29 μ . Eighteen of these have diameters of *ca.* 36 μ . The relative transparency of these particles indicates that they are probably disk-shaped. A centrifuge determination of the size of these molecules led to a diameter of 24 μ , (on the assumption of spherical shape), considerably smaller than the average of the directly measured diameters.

"The results indicate that the electron microscope is very useful in the elucidation of the sizes and particularly the shapes of the larger protein molecules. In the case of molecules which are essentially spherical in shape, such as, for example, bushy stunt virus and probably also *Limulus* hemocyanin, the agreement between molecular sizes estimated by indirect methods and those estimated directly from electron micrographs is excellent. The fact that in one and perhaps two cases the molecular sizes estimated by means of the electron microscope are not in accord with those estimated by indirect methods based on the assumption of a spherical shape is a probable indication that the latter assumption is not justified. Discrepancies between molecular weights estimated by different indirect methods are usually regarded as being due to hydration, to asymmetry, or to both, and in most cases it is not possible to determine by the indirect methods which factor is the more important. For the larger protein molecules it is now possible to determine directly by means of the electron microscope the cases of molecular asymmetry due to a rod-like shape, such as occurs, for example, in tobacco mosaic virus, and it is possible to secure some measure of information regarding disk- or plate-like shapes, such as appear to occur in *Viviparus* hemocyanin and probably also in *Busycon* hemocyanin. This type of information, which can be provided by electron micrographs, should make it possible to evaluate better the relative importance of hydration and asymmetry in molecular weight estimations of the larger protein molecules."

In considering the application of the electron microscope in this field, the discussion of von Ardenne¹⁷ is of some interest. It is concerned with the limiting dimensions of organic particles which may be detected and resolved with present instruments. The need for specimen-supporting films of smaller thickness-density than are commonly used is made evident, for in this discussion it is shown that the dimensions of the smallest observable particles depend critically upon the contrast in the image.

Plant Virus Reactions. Of the numerous biological and chemical reactions which have been demonstrated in the past three years, two typical examples will be reviewed to illustrate the data provided by electron micrographs. For a more extensive discussion, the reader is referred to the paper in this volume by Lauffer and Stanley.

As suggested by Kausche,⁸⁹ the Lange gold sol reaction may be used as a test to distinguish between the virus proteins of diseased potato and tobacco plants. Their identities may be established by the observation of the precipitation which follows the addition of a red-colored gold sol to suspensions of viruses obtained from diseased plants (see also ¹²⁷). On adding a red sol to a neutral suspension of potato-X virus, a voluminous red-colored sediment is produced. A precipitate is difficult to obtain by adding the red sol to a neutral suspension of tobacco mosaic virus, but if sufficient sol is added, a precipitate is formed which is blue in color. The red-colored precipitate characteristic of the potato-X virus reaction may be obtained, however, by add-

FIGURE 45a. Blue colored precipitate in neutral suspension of tobacco mosaic virus.

ing red sol to an acid suspension of the tobacco mosaic virus. In the latter case, it is difficult to separate the protein from the gold particles by centrifuging. This indicates that the gold particles are adsorbed on the protein molecules.

Kausche and Ruska⁹² succeeded in demonstrating this precipitin reaction and thereby in explaining the observed results. The blue-colored precipitate of the sol in the neutral suspension of tobacco mosaic virus is illustrated in Fig. 45a (Fig. 3⁹²). The gold crystallites have aggregated into larger particles which settle out independently of the protein molecules. Since there is no evidence of a physical bond between the gold aggregates and the protein molecules, the ease of their separation by centrifuging may be explained. The red-colored precipitate which is obtained with the neutral potato-X virus and the acid tobacco mosaic virus suspensions is illustrated in Fig. 45b (Fig. 7⁹²). In this case, the adsorption of the gold particles on the protein molecules is clearly evident. Although the resultant aggregates are more massive than either the gold particles or protein molecules, the spacing between the gold particles is much larger than in the case in which they are aggregated by themselves, and the characteristic red color is maintained in the precipitate. Because of the strong attractive bond between the gold and protein particles, separation by centrifuging is difficult to carry out.

Of greater interest are the precipitin reactions indicating the inactivation of the virus proteins by antibodies which are generated in the blood stream of animals to combat disease. The first report of the investigations of Anderson and Stanley² is an excellent example of the work being carried on.

The absence of observable interaction between the blood serum of a normal rabbit with tobacco mosaic virus may be inferred from the appearance and dimensions of the virus molecules occurring in a suspension of tobacco mosaic virus to which had been added the normal serum. A specimen is illustrated in Fig. 46a (Fig. 3²). The rod-shaped tobacco mosaic virus particles are identical with the normal virus particles shown in Fig. 43.

On adding a purified anti-serum obtained from a rabbit into which the virus previously had been injected, Anderson and Stanley were able to demonstrate the antibody-antigen reaction. The adsorption of the antibodies on the virus proteins may be inferred from the increased width and loss of sharp boundaries of the rod shaped

FIGURE 45b. Red colored precipitate in acid suspension of tobacco mosaic virus.⁹²

FIGURE 46a. Normal serum and tobacco mosaic virus.²

particles shown in Fig. 46 (b) (Fig. 4²). The characteristic aggregation leading to precipitation is also demonstrated by the aggregates of enlarged molecules. The large black particle appearing in this micrograph is an impurity introduced in the specimen to facilitate focusing of the image. Without this, focusing is difficult because of the low contrast in the image between the specimen particles and the background consisting of the supporting film.

Collagen. The utility of the electron microscope for the investigation of organic structures composed of organized aggregates of long-chain molecules has been demonstrated recently by Schmitt, Hall and Jakus.¹⁴⁸ The structure of collagen fibers has been one of the most difficult to elucidate by means of the customary techniques employed in the study of large molecules. Attempts to describe the configuration of the polypeptide chains in terms of the keratin chain models have been unsatisfactory. The difficulty is partially attributed to the diversity of the R groups in the side chains

of the amino acid residues. This prevented the preparation of clear x-ray patterns from which the manner of folding or coiling of the chains could be interpreted. It is enhanced further by the abnormal extensibility and contractility of collagen fibers relative, for example, to wool. A distinguishing feature in the x-ray patterns of collagen, known for some years, is the existence of diffraction maxima indicating a periodicity of large spacing in the direction of the fiber axis. The latter periodic spacing, well above the resolving limit of the electron microscope, suggested the use of this instrument for the direct observation of collagen fibers. A detailed study of collagen, involving methods of preparation, determination of composition, and structure

FIGURE 46b. Tobacco mosaic virus in presence of anti-serum.²

analysis by polarization, x-ray and electron-optical methods was therefore initiated by Schmitt.

In preliminary publications by Schmitt, Hall and Jakus,^{71, 148} electron micrographs of collagen fibers from a variety of sources, including tail tendon, tendo Achilles, dermis of skin, interfibrillary connective tissue of nerve, cornea, spleen and ligamentum nuchae have been illustrated. Fibers for the specimens were obtained either by teasing small fibers in water or by dissolving the materials in acetic acid and reprecipitating the fibers by neutralization.

Typical structures observed in the fibers from specimens from all of the above sources is illustrated in Fig. 47 (Figs. 7, 8, 9¹⁴⁸). The fibers are cross-striated with relatively opaque bands (A bands) and transparent bands (B bands) extending uniformly across them. The uniform optical density along the lengths of the A and B bands, as well as the appearance of folded fibers, indicate that the fibers have a sensibly uniform thickness and may be regarded as ribbon-shaped. The spacing between successive A or B bands was found to vary from about 400 Å to 1000 Å in fibers from different preparations. In unstretched individual fibers, however, the spacing is reasonably constant. On making a distribution curve of the fiber axis spacing from measurements in a single preparation of rat-tail tendon, the curve was found to have a sharp maximum at 640 Å. X-ray diffraction studies, by Bear,³² of similarly prepared and air-dried specimens of collagenous materials revealed a fiber axis spacing in the range 638-648 Å, thus verifying the conclusion that the large fiber axis structural periodicity inferred from x-ray observations is identical with the striated structure revealed in the electron micrographs. It is also evident from these observations that the preparation of the specimens for electron-microscope observation causes appreciable contractions and extensions in the single isolated fibers.

The latter fact, together with the discovery, in several specimens, of greatly extended fibers, provide new data for the analysis of the molecular organization in collagen. One of the stretched fibers is shown at the right in Fig. 47 (Fig. 9¹⁴⁸). At the upper end of this stretched fiber, the spacing between successive A bands has been increased to nearly 6,000 Å, nine times the average normal spacing of 640 Å. A study of the widths of the A and B bands shows that the A bands suffer a greater

FIGURE 47. Collagen Fibrils. 7, fibrils from tail tendon of Kangaroo; 8, Beef Tendon Achilles fibrils; 9, fibril from rat tail tendon, enormously stretched by peeling back of collodion supporting film.¹⁴⁸

extension than the B bands. This indicates that there is a greater degree of folding or coiling of the molecular chains in the A bands. The long-range extensibility of the fibers, revealed in the latter micrograph, is at variance with the extensibility exhibited by collagen fibers in intact tendons, in which an extension in excess of 10-15 per cent results in rupture.

"Any satisfactory theory of collagen structure must account for the above-mentioned facts. Most of the suggestions thus far offered are inadequate, since they are based on the assumption that there is little or no folding of the elementary columns. The "fringe" theory of Hermann, Gerngross and Abitz ('30, '32) pictures crystalline bundles of parallel chains which are joined together by the irregularly disposed chains into which the bundles fray. This theory is subject to certain objections such as those raised by Küntzel and Prakke ('33), and fails to account either for the regularity of the banding or for long range extensibility. Huggins ('42) proposed a structure consisting essentially of an assembly of parallel two-dimensional nets composed of spiral chains bonded to each other by NHO bridges. While this structure provides for some extensibility it offers no clues regarding the structural basis of the A and B bands.

"The experiments on very long range extensibility suggest that the folding, particularly in the A bands, may be much more extensive than that pictured by Astbury as characterizing the alpha state in keratin. It seems probable that the foldings characteristic of the A and B bands are imposed on the protofibrils by the steric requirements and interactions of the constituents amino and imino acid residues. Since the folding appears to be different in the A and B bands it is possible that the amino acid composition of the protofibrils may be different in these two regions."

"Wyckoff and Corey ('36) state that the x-ray long spacings obtained from collagen precipitated from acid solutions by addition of salt are identical with those of intact tendon. From this they conclude that collagen is not composed of bundles of indefinitely extended polypeptide chains, but rather of very large particles which are arranged in crystalline array in tendon and which retain their identity in acid solution. Addition of salt causes the particles to be recruited into a regular crystalline array characteristic of intact tendon. It was of interest, therefore, to determine whether the existence of these large particles in acid solution could be demonstrated by the electron microscope method.

"Thus far no such discrete particles have been observed in preparations made by drying acetic acid solutions of collagen (pH 3.2). From this little more can be concluded than that the protofibrils have a width smaller than the resolving power of the EM (*ca.* 50 A) or a thickness so small that the contrast is too low to make the units visible."¹⁴⁸

In discussing the difference in extensibility between dried individual fibers and intact tendon, Schmitt *et al*, assume that the fibers in intact tendon have a finite length. When a tendon is ruptured, a shearing of fibers occurs before sufficient force can be exerted to demonstrate the long-range extensibility of the individual fibrils. Such a mechanism might be verified with the electron microscope by measurement of the dimensions of the frayed fibrils of a ruptured small tendon and obtaining force-extension curves for individual fibrils as demonstrated qualitatively in their paper.

Rheological Properties of Simple and Colloidal Systems

HENRY EYRING AND RICHARD E. POWELL

Princeton University, Princeton, New Jersey

Introduction

Usually the diffusion coefficient, D , of colloidal particles in dilute solutions may be assumed to obey the Stokes-Einstein equation

$$D = \frac{kT}{6\pi r\eta} \quad (1)$$

or the appropriate modifications of Equation (1) which take into account the shapes of the particles. Here k , T , r and η are the Boltzmann constant, the absolute temperature, the radius of the particle and the viscosity of the medium, respectively. The viscosity, η , of a medium was shown by Einstein to be

$$\eta = \eta_0 (1 + 2.5\phi) \quad (2)$$

where ϕ is the volume fraction of large spherical particles in a medium of small molecules of viscosity η_0 . To the approximation that these relationships hold, the theory of diffusion of large particles is reduced to the theory of the viscosity of the medium. We shall be concerned here with presenting some recent developments in the theory of viscosity of liquids, and of the diffusion of particles when the diffusing particles approach in size the molecules of the dispersing medium.

The Statistical Mechanical Theory of Reaction Rates

We only sketch this theory very briefly here, and refer the interested reader to a short exposition by Walter and Eyring,¹ to the book on the subject by Glasstone, Laidler and Eyring,² or to some standard text on statistical mechanics.³

A system of s atoms joined into a single molecule or into several molecules has a chance

$$P_i = a e^{-\epsilon_i/kT} \quad (3)$$

of being in a particular unique state of energy ϵ_i , provided this system is in equilibrium with its surroundings at a temperature T . The proportionality factor a is uniquely determined by the requirement that the sum of the probabilities, p_j , over all the possible states, initial and final, should add up to unity, *i.e.*, $1 = \sum_j a e^{-\epsilon_j/kT}$, or

$$a = \frac{1}{\sum_j e^{-\epsilon_j/kT}} \quad (4)$$

Thus for the equilibrium

we can write

$$\frac{\sum_f P_f}{\sum_i P_i} = \frac{n_I^{l_1} n_J^{l_2} \dots}{n_A^{m_1} n_B^{m_2} \dots} = \frac{\sum_f a e^{-\epsilon_f/kT}}{\sum_i a e^{-\epsilon_i/kT}} = \frac{\sum_f e^{-\epsilon_f/kT}}{\sum_i e^{-\epsilon_i/kT}} \quad (6)$$

or

$$K = \frac{\left(\frac{n_I}{V}\right)^{l_1} \left(\frac{n_J}{V}\right)^{l_2} \dots}{\left(\frac{n_A}{V}\right)^{m_1} \left(\frac{n_B}{V}\right)^{m_2} \dots} = \frac{\sum_f \frac{e^{-\epsilon_f/kT}}{V^{l_1+l_2+\dots}}}{\sum_i \frac{e^{-\epsilon_i/kT}}{V^{m_1+m_2+\dots}}} = \frac{F_f}{F_i} \quad (7)$$

In the stoichiometric equation (5) we have indicated that m_1 molecules of type A react with m_2 molecules of type B, etc., to give l_1 molecules of type I, l_2 molecules of type J, etc. In equation (6), n_A indicates the actual number of molecules of type A in volume V for our system at equilibrium, the other n 's having an analogous significance for the other types of molecules. The summation over subscript f indicates that the summation is to be over final states, while i has the same significance for initial states. This is perhaps made clearer by looking at the schematic diagram of Figure 1.

FIGURE 1. The energy relations of a reacting system.

In Equation (7), K is the equilibrium constant and $F_f = \frac{\sum e^{-\epsilon_f/kT}}{V^{l_1+l_2+\dots}}$ is defined

as the *partition function* at unit concentration for the final state, while F_i is the partition function for the initial state. Because ϵ_f can to a good approximation be written as the sum of $3s$ energies, one for each degree of freedom, the final partition function F_f can be written as a product of $3s$ well-known partition functions. The same is true of the initial partition function F_i .

Now this same sort of consideration enables us to write the expression for the rate of reaction. Thus if we describe an activated state by the requirement that the

system composed of s atoms have its reaction coördinate within the length δ at the top of the potential barrier, we have for the corresponding equilibrium constant

$$K_a = \frac{F_a}{F_i} \equiv \frac{F^\ddagger \frac{(2\pi m^\ddagger kT)^{\frac{1}{2}} \delta}{h}}{F_i} \equiv K^\ddagger \frac{(2\pi m^\ddagger kT)^{\frac{1}{2}} \delta}{h} \quad (8)$$

Thus the concentration of systems, c_a , lying in the length δ is

$$c_a = K_a (A)^{m_1} (B)^{m_2} \dots \quad (9)$$

In Equation (8) the partition function for the activated state F_a can be factored into

the partition function for the reaction coördinate $\frac{(2\pi m^\ddagger kT)^{\frac{1}{2}} \delta}{h}$, where h is Planck's constant and m^\ddagger is the reduced mass for this coördinate, and into the partition function F^\ddagger for the remaining $(3s - 1)$ degrees of freedom. $(A) \equiv \left(\frac{n_A}{V}\right)$ is the concentration of molecules of type A.

We now proceed exactly as though we were trying to calculate the number of automobiles passing over a hill. We multiply the concentration, c_a , of the activated systems by the mean velocity, $\sqrt{kT/2\pi m^\ddagger}$, then divide by the length δ , and finally multiply by a transmission coefficient κ which takes care of the chance that a system may turn back after passing the crest of the hill. We thus obtain the velocity of reaction

$$\text{rate} = \kappa C_a \sqrt{\frac{kT}{2\pi m^\ddagger}} \frac{1}{\delta} = \kappa K^\ddagger \frac{kT}{h} (A)^{m_1} (B)^{m_2} \dots \quad (10)$$

Now since the specific reaction rate constant k' is defined by the equation

$$\text{rate} = k' (A)^{m_1} (B)^{m_2} \dots \quad (10a)$$

we have by comparing Equation (10) and Equation (10a)

$$k' = \kappa \frac{kT}{h} K^\ddagger \quad (11)$$

We now apply this general expression for the rate of a reaction to the velocity of motion forward of a single molecule, or an aggregate of molecules, in a condensed phase when driven by some external potential. Since two molecules cannot simultaneously occupy the same space, it is natural to suppose that a prerequisite of a molecule's moving forward is that there be an empty space into which to move. While this is in fact true, as we shall see later, we shall develop a general formulation independent of any particular mechanism. Suppose that when no external potential is applied, a molecule on the average jumps k'' times per second, counting all possible directions, and that the average distance jumped is λ . Now if a potential is applied which does an amount of work, W , on a molecule (or aggregate) when it moves in the direction of the field through a distance corresponding to that lying between the normal and the activated states, we have for the average velocity, U , in the direction of the field

$$U = \frac{\int_0^\pi k'' \lambda \cos \theta e^{-W \cos \theta / kT} \sin \theta d\theta}{\int_0^\pi \sin \theta d\theta} = k'' \lambda \left\{ \left(\frac{kT}{W} \right) \cosh \frac{W}{kT} - \left(\frac{kT}{W} \right)^2 \sinh \frac{W}{kT} \right\} \quad (12)$$

Now when W/kT is very small we expand the exponential terms in Eq. (12) and obtain

$$U = k'' \lambda \frac{W}{3 kT} \quad (13)$$

The condition that W/kT is small is easily satisfied for many rate processes, *e.g.*, viscous flow, diffusion, ionic conductance, and rotation of polar molecules in a fluid. A molecule in a simple liquid jumps to a new position some 10^9 times per second, and only one jump in several hundred is produced by the applied potential. It is apparent that under these conditions there will be no "saturation effects." On the other hand, such rate processes as solid friction and plastic flow have a very large value of W/kT ; these processes are treated in a later section.

The result of Equation (13) has usually been obtained in a somewhat different way. Let us suppose that, when no force is acting, a molecule or aggregation of molecules jumps forward or backward k' times per second through the distance λ . The result is a zero net velocity. Now if a force is applied which does an amount of work, W , on the system when it moves forward from the normal to the activated state, it will do an amount of work $-W$ for a similar motion in the back direction. The net velocity then is

$$U = k' \lambda (e^{W/kT} - e^{-W/kT}) = k' \lambda 2 \sinh \frac{W}{kT} \quad (14)$$

When W/kT is much less than unity we obtain

$$U = k' \lambda \frac{2W}{kT} \quad (15)$$

This becomes identical with Equation (13) when we make the substitution $k' = k''/6$, which corresponds to saying that one-sixth of the molecules normally moving in all directions move forward. When W/kT is moderately large, Equation (12) and Equation (14) lead to slightly different results.

The Viscosity of Liquids

Viscous flow is the particular example of a transfer process in liquids where the driving potential is a shearing force, the work W being done by the force f acting upon an area $\lambda_2 \lambda_3$ through a distance of $\lambda/2$.⁴ The velocity equation is then

$$U = k' \lambda \frac{f \lambda_2 \lambda_3 \lambda}{kT} = \frac{f \lambda_2 \lambda_3 \lambda^2}{h} e^{-\Delta F^\ddagger/kT} \quad (16)$$

Since viscosity is defined by the relation

$$\eta = \lambda_1 / fU \quad (17)$$

the viscosity equation becomes

$$\eta = \frac{\lambda_1 h}{\lambda_2 \lambda_3 \lambda^2} e^{\Delta F^\ddagger/kT} \quad (18)$$

The distances λ_1 , λ_2 , and λ_3 are lattice distances between molecules in the liquid. As the temperature rises, the molecular volume V/N of the liquid will increase. However, according to our present theory of liquid structure, this net expansion is due almost entirely to the presence of more and more "holes" in the liquid, the lattice expansion being comparatively small. The value of the product $\lambda_1 \lambda_2 \lambda_3$ may then be taken as constant and equal to the molecular volume V_s/N of the solid. The volume

V/N of the liquid is probably a somewhat poorer approximation, although the computed viscosity is quite insensitive to whether V or V_* is used.

The distance λ which a molecule jumps is certainly of the order of the other lattice distances, and if we make the approximation that $\lambda = \lambda_1$, Equation (18) takes the form

$$\eta = \frac{Nh}{V_*} e^{\Delta F^\ddagger/kT} \quad (19a)$$

or the equivalent forms

$$\eta = \frac{Nh}{V_*} e^{-\Delta S^\ddagger/k} e^{\Delta H^\ddagger/kT} \quad (19b)$$

$$\eta = \frac{Nh}{V_*} e^{-\Delta S^\ddagger/k} e^{\Delta E^\ddagger/kT} e^{P\Delta V^\ddagger/kT} \quad (19c)$$

The first requirement which Equation (19) satisfies is that it gives an exponential dependence on temperature, so that the logarithm of viscosity should plot as a straight line against $1/T$. This experimental result was found by Arrhenius,⁵ de Guzman,⁶ and Andrade.⁷

From the experimental data any of the thermodynamic properties of the activated state can readily be computed—for example, the free energy change of going from normal to activated states (ΔF^\ddagger) is calculated from the viscosity itself, the heat change (ΔH^\ddagger) from the temperature coefficient, the volume change (ΔV^\ddagger) from the pressure coefficient, the entropy change ($\Delta S^\ddagger = (\Delta H^\ddagger - \Delta F^\ddagger)/T$) and the energy change ($\Delta E^\ddagger = (\Delta H^\ddagger - P\Delta V^\ddagger)$ by difference, the change in heat capacity by $d(\Delta H^\ddagger)/dT$, the change in compressibility by $d(\Delta V^\ddagger)/dP$, and so on. We may emphasize that even though the activated (flowing) molecular state has the short life-time of about 10^{-13} second, it is a real state with perfectly definite properties of its own.

It is instructive to compute the properties of a molecule in the activated state and correlate them with other properties of the liquid. The results of several such studies on viscous flow will be here summarized.^{8,9,10} To facilitate comparison with other thermodynamic properties, the thermodynamic properties of activation (ΔF^\ddagger , ΔH^\ddagger , etc.) have been computed in calories per mole instead of ergs per molecule.

The volume change of activation ΔV^\ddagger is about $1/4$ or $1/8$ the volume of a molecule, for a number of simple liquids. This has been interpreted as the volume of the hole which must be provided for a molecule to flow. For molten metals the volume of the hole is about $1/8$ the volume of the metal ion, in agreement with other evidence that in molten metals the flowing individual is the ion instead of the atom.

The energy change of activation ΔE^\ddagger is equal to the heat change of activation ΔH^\ddagger at normal pressures, since the pressure effect is negligible. It is about $1/3$ or $1/4$ the heat of vaporization for a number of non-associated organic liquids. The energy required to form a hole may well be expected to be some fraction of the energy of vaporization, since the same type of bonds within the liquid are broken in both processes. If the hole were the full size of a molecule, the full energy of vaporization would be required to make a hole: it is thus apparent that a hole necessary for viscous flow is smaller than a molecule. Typical heats of activation are for ether 1.6 kilocalories, and for hexane 1.8 kilocalories.

If the liquid molecules fit extremely well in the normal state, it will be more expensive in energy for flow to occur, even after a hole has been provided. High heats of activation are then to be expected (1) in cycloparaffins and in polycyclic aromatic hydrocarbons, where the molecules are flat and therefore pack together well in the normal state, and (2) in hydrogen-bonded liquids, where these bonds must be broken before a molecule can flow. It is well known that the viscosity of lubricating oil

containing a high proportion of naphthenes and aromatics is more temperature-dependent than that of paraffin-base oils. The heat of activation for naphthalene is 6.3 kilocalories. As typical hydrogen-bonded liquids we may mention isobutyl alcohol ($\Delta H^\ddagger = 5.5$ kcal) and glycerol ($\Delta H^\ddagger = 14.8$ kcal).

When the viscosities of successively longer and longer straight-chain hydrocarbons are measured, the heat of activation does not increase without limit, but instead approaches asymptotically the value of about 8 kcal.¹¹ Even more striking is the viscosity behavior of linear polyesters, where the heat of activation remains sensibly constant at 8.4 kcal over a range of molecular weight of 500 to 10,000.¹² These phenomena have been interpreted as demonstrating that long molecules flow by segments of length about 20 to 25 chain atoms.¹¹ This segment model has also received considerable support from investigations on properties other than viscosity, such as annealing of polyamides,¹³ rates of polyesterification,¹⁴ thermodynamic properties like melting point and osmotic pressure,¹⁵ and dielectric dispersion of polymer solutions.¹⁶

The entropy change of activation ΔS^\ddagger might be expected to be near zero for a simple liquid, since the flowing molecule is substantially the same as the normal molecule, all its degrees of freedom being unchanged except that one vibration has become a short translation. The experimental fact is that the entropy of activation for many substances is small, of the order of 0 to -3 entropy units. Those liquids which show large heats of activation (plate-like and hydrogen-bonded) also show large positive entropies of activation: naphthalene, $\Delta S^\ddagger = 6.7$ E.U.; glycerol, $\Delta S^\ddagger = 26$ E.U. These liquids are in the normal state, probably held relatively fixed by their van der Waals or hydrogen bonds. Although a flowing molecule must expend considerable energy to break such bonds, it gains a substantial amount of rotational entropy in its flowing state. In fact, the heat and the entropy changes largely compensate for each other.

The long straight-chain molecules which move by segments have an additional negative entropy term which probably arises as follows: Many of the jumps made by a segment will be unprofitable, for the molecule will progress only when all segments by chance jump in the same direction. The longer a molecule is, the less is the chance of all its segments jumping in the same direction, and this effect introduces a term $\Delta S^\ddagger = -\text{const. } Z^{1/2}$, where Z is the chain length. The effect of chain length on the viscosity of polyesters was first found experimentally,¹² and was later deduced from theoretical considerations, even the value of the constant being estimated.¹¹

As a result of the tendency for heat and entropy changes to compensate, the free energy change of activation ΔF^\ddagger shows much less irregularity than either the heat or the entropy change. It is determined almost entirely by the energy necessary to create a hole in the liquid, and may be estimated fairly closely for a wide variety of liquids by taking it as $1/2.45$ th of the energy of vaporization.¹⁰

As an illustrative example, all the thermodynamic properties of activation for viscous flow will be computed for a Pennsylvania, an Oklahoma, and a California lubricating oil. The data are those of R. B. Dow.¹⁷ While the oils are of course mixtures, they are well enough defined to give consistent and easily interpretable results.

The logarithm of viscosity was plotted against pressure, giving good straight lines (Figure 2) from whose slope the value of ΔV^\ddagger was obtained (Table 1).

Table 1

| | Pennsylvania | Oklahoma | California |
|-------------|--------------|----------|------------|
| 38° C. | 50.9 cc | 59.9 cc | 79.0 cc |
| 54 | 46.1 | 51.5 | 61.5 |
| 99 | 36.6 | 41.0 | 54.1 |

Since lubricating oils approximate a C_{25} hydrocarbon, of density 0.86, the molal volume is about 430 cc. The value of ΔV^\ddagger for the Pennsylvania oil at 38°C is thus about 1/8.5th the volume of a molecule, in agreement with expectation. It is interesting to mention that according to the segment theory of long molecules, a paraffin, however long, will move in segments of about 25 atoms in length. Thus the activation volume would not be expected to increase indefinitely with increasing chain length, but to approach a limiting value of approximately 50 cc. Experimental data

FIGURE 2. Effect of pressure on the viscosity of lubricating oils.

Circles Pennsylvania oil
Squares Oklahoma oil
Triangles California oil

are not at present available to test this prediction. The value of ΔV^\ddagger for the California oil is particularly large, probably because of the larger activation volumes of the naphthenes (cyclic hydrocarbons) which California oil is known to contain.

It is to be noted that ΔV^\ddagger decreases regularly with increasing temperature. At higher temperatures there are more holes in the normal liquid, so that less have to be introduced to go to the activated state. The value of ΔV^\ddagger must in fact decrease steadily with rising temperature, until it becomes zero at (or somewhat above) the critical temperature, for it is well known that the viscosity of a perfect gas is independent of pressure.

The logarithm of viscosity (extrapolated to zero pressure) was plotted against $1/T$, and from the slope of the line ΔE^\ddagger was obtained. These values of ΔE^\ddagger , together with the corresponding values of ΔF^\ddagger and ΔS^\ddagger , are assembled in Table 2.

Table 2

| | Pennsylvania | Oklahoma | California |
|---------------------------------|--------------|----------|------------|
| ΔE^\ddagger (kcal)..... | 7.66 | 7.78 | 9.32 |
| ΔF^\ddagger (kcal)..... | 7.05 | 7.13 | 8.22 |
| ΔS^\ddagger (E.U.)..... | 2.0 | 2.1 | 3.5 |

Note that while the Pennsylvania and Oklahoma oils have ΔE^\ddagger near the limiting value for an infinitely long straight hydrocarbon, the California oil is considerably

higher than the limit—again because of its naphthenic hydrocarbons. Note also that the increased ΔE^\ddagger is partially compensated by an increase in ΔS^\ddagger for the California oil.

The foregoing studies on viscosity have led to a definite model for the process of viscous flow. The molecules in a solid are analogous to a crowd of people packed closely together: each individual must stand in his place, and can only breathe. When the solid melts to a liquid, a finite number of holes are introduced, giving an increase in volume—a man in the crowd will now occasionally have an empty position next to him, and can step into the new place. An observer watching from above could see that any one individual will move to and fro many times, in random directions, while the crowd as a whole does not move. However, if some force is applied so that the individuals move north slightly more often than south, the crowd will on the average move northward.

From this qualitative picture of liquid structure, the viscosity data have provided a quantitative measure of the size of holes, the energy necessary to create them, and the effect of such phenomena as van der Waals and hydrogen bonding. In addition, the same model of liquid structure can be applied with success to a quantitative calculation of all the thermodynamics of liquids. The application to liquid neon, argon, krypton, xenon, nitrogen, sodium, mercury and benzene has been made, and many more liquids are at present being studied. The detailed results are published elsewhere:^{18,19} it is here sufficient to say that by using only the physical properties of the solid, it has been possible to calculate the melting constants, critical constants, vapor pressure, density, and heat capacity of the liquid with considerable accuracy.

Viscosity of Surface Films

The viscous flow of molecules within a unimolecular film is completely analogous to the viscous flow of molecules in bulk. The derivation of the viscosity equation proceeds exactly as in the foregoing section, so the details will not be repeated here (see ²⁰). One obtains the result

$$\eta = \frac{h}{a} e^{\Delta F^\ddagger/kT} \quad (20)$$

Equation (20) is identical with the usual viscosity equation, Equation (19), except that the area a of a molecule has now replaced the volume V_s/N of a molecule. This is of course because surface forces are defined and measured in only two dimensions.

The viscosity data for surface films are less plentiful than for liquids in bulk. The free energy of activation, ΔF^\ddagger , has been computed for several condensed liquid films, and the values are assembled in Table 3.²⁰

Table 3

These free energies are approximately twice as high as those for the same liquids in bulk.

The heat of activation for simple films would be expected to be very nearly the same as the free energy of activation. The heat of activation for films of arachidic acid (C₂₀) is about 15 kcal, as estimated from preliminary measurements.²¹

The surface change of activation, Δa^\ddagger , is the analog in films of the volume change of activation in liquids, and it is as before evaluated by plotting the logarithm of

viscosity against pressure. Its value is of the order of the surface of one molecule, or about 22 \AA^2 ; the experimental values vary from 31 \AA^2 for arachidic acid (C_{20}) to 56 \AA^2 for palmitic acid (C_{16}).²¹ These high values are to be contrasted with the low values of the volume change of activation for liquids in bulk (see page 240). We shall offer an explanation below for these and certain other anomalies.

When the pressure vs. area of certain films is investigated, an additional phase is found between the "condensed liquid" and the "solid" phases. This phase is less compressible than the liquid and more compressible than the solid, and has been called the "plastic solid."²² The viscosity-vs.-pressure curves also exhibit marked changes at approximately the same places at which the area vs. pressure curves have breaks. From such data a phase diagram (temperature vs. pressure) has here been sketched for a film of octadecanol (Figure 3).*

FIGURE 3. Phase diagram of an octadecanol film.

A region somewhere at the extreme right of the diagram represents the solid phase. The region at the left of the diagram represents the condensed liquid phase. The viscosity of this condensed liquid film is closely parallel to that of a normal liquid; it increases with increasing pressure and decreases with increasing temperature. The intermediate portion of the diagram represents the plastic solid phase. In the low-temperature region, this also behaves like a normal liquid, the viscosity increasing with increasing pressure and decreasing with increasing temperature. However, in the high-temperature region the viscosity behavior of the plastic solid is quite different: (1) the viscosity is sensibly independent of pressure; (2) it increases with increasing temperature; (3) the viscosity of the plastic solid (high-temperature form) may be either higher or lower than that of the condensed liquid. If it is lower, the viscosity-vs.-pressure curve has a negative slope in the region between condensed liquid and plastic solid; if it is higher, the viscosity-vs.-pressure curve is abnormally

* We are indebted to Prof. W. D. Harkins and Dr. Edward Boyd for the viscosity and pressure-area data from which Figure 3 was constructed.

steep. Similarly, if the viscosity of the plastic solid (high-temperature form) is less than that of the plastic solid (low-temperature form), the viscosity-vs.-pressure curve in the region between them is abnormally steep. An explanation for these phenomena is now to be sought.

Viscosity anomalies for liquids in bulk are known to be associated with highly organized structure. Thus the viscosity of most liquids increases with an increase in pressure; water, which is known to be hydrogen-bonded, behaves in the opposite way within a certain range of pressures: increase in pressure decreases the viscosity. One expects more of these anomalies in surfaces, with their greater structural complexities.

We shall now develop one example of such a possible complexity. Suppose that on the surface the mole fraction N_1 of the molecules are oriented in some one way, and the remaining N_2 are oriented in another way. Let ΔF be the difference in free energy between these two states. Then we have the relations:

$$N_1 + N_2 = 1 \quad (21a)$$

$$N_2/N_1 = e^{-\Delta F/kT} \quad (21b)$$

whence

$$N_1 = \frac{1}{1 + e^{-\Delta F/kT}} \quad (21c)$$

$$N_2 = \frac{1}{1 + e^{\Delta F/kT}} \quad (21d)$$

Now the two forms may differ in viscosity. If the mixture law for viscosity

$$\eta = \frac{h}{a} e^{(N_1 \Delta F_1^\ddagger + N_2 \Delta F_2^\ddagger)/kT} \quad (22)$$

applies (as it does very accurately for liquids in bulk,¹⁰ and cannot in any event be far wrong) we obtain, with a little algebraic calculation, the relations

$$RT \left(\frac{\partial \ln \eta}{\partial P} \right)_T = N_1 \Delta a_1^\ddagger + N_2 \Delta a_2^\ddagger + \frac{\Delta a}{2 \left(1 + \cosh \frac{\Delta F}{kT} \right)} \frac{\Delta F_1^\ddagger - \Delta F_2^\ddagger}{kT} \quad (23)$$

$$R \left(\frac{\partial \ln \eta}{\partial 1/T} \right)_P = N_1 \Delta H_1^\ddagger + N_2 \Delta H_2^\ddagger + \frac{\Delta H}{2 \left(1 + \cosh \frac{\Delta F}{kT} \right)} \frac{\Delta F_1^\ddagger - \Delta F_2^\ddagger}{kT} \quad (24)$$

Where the symbols with the superscript \ddagger indicate, as usual, the change in going from the normal to the activated state, and the symbols without superscript indicate the change between species 2 and species 1. As an illustration, the logarithm of viscosity has been plotted against pressure for a hypothetical liquid with $\Delta F_1^\ddagger = 4000 + 0.33P$ calories, $\Delta F_2^\ddagger = 2000 + 0.33P$ calories, $\Delta A = 1000$ calories and $\Delta V = 100 \times 10^{-24}$ cc, in Figure 4. (The numerical values are of course arbitrary, and Figure 4 must be regarded as schematic.) It is seen that even though the viscosities of both species 1 and 2 are increased with pressure, the viscosity of the mixture may decrease with rising pressure because of the effect of pressure in shifting the equilibrium in the direction of the more fluid molecules. This produces the negative slope of Figure 4. If we had assumed species 2 to be more viscous than species 1, instead of less so, we would have obtained an abnormally rapid rise of viscosity with pressure in the region of shifting equilibrium. Entirely analogous results will be obtained for the variation of viscosity with temperature, as Equation

(24) shows. Thus we believe that the rapid variations with pressure or temperature exhibited by octadecanol films is to be explained in terms of such shifts in equilibrium between two types of surface molecules. The same explanation may be offered for the unusually high values of Δa^\ddagger for the long-chain acids.

The "plastic solid" octadecanol surfaces at high temperature and pressure have a viscosity which is independent of pressure, increases with temperature, and is

FIGURE 4. Effect of a shifting equilibrium on viscosity. Schematic.

furthermore thixotropic, *i.e.*, the viscosity decreases with increased velocity of motion of the viscometer disc over the surface. This is the type of behavior expected if at these high pressures the slippage changes from (mechanism one) that of one surface molecule past another to (mechanism two) a slippage between the surface atoms and the disc. In this case compressing the surface atoms would tend to inhibit mechanism one and bring about a shift to mechanism two, which latter would show no effect of lateral pressure on the viscosity, since the motion of film molecules will no longer be involved in the shearing process. The loss of momentum from the shear plane is now presumed to take place by momentum transfer normal to the surface, much as in the gas phase, and this loss in momentum would be expected to increase with temperature as for a gas, also to become less at high velocities since increased velocity lessens the time in which momentum can be dissipated.

The foregoing explanations, even if they should prove to be in part inapplicable to this particular example, indicate some things which must be taken into consideration in understanding the problems of surface viscosity.

Film Lubrication

Lubrication by thick films of liquids has been extensively considered by the methods of hydrodynamics, and the effectiveness of lubrication expressed in terms of the dimensionless quantity $N\eta/W$, where N is the speed, η the viscosity, and W the load.²³ A desirable lubricant for thick film lubrication is therefore one of high viscosity.

Simple liquids usually have viscosities of about 2 centipoises at their melting points. This is because in the process of melting there is an increase in entropy due

to the introduction of about 0.8 mole of new equilibrium positions (or holes) per mole of matter, giving all simple liquids about the same concentration of holes. As we have seen previously, the free energy of activation for viscous flow arises almost entirely from the necessity of having holes; hence to a good approximation substances with an equal number of holes will have an equal fluidity. As the temperature is raised there will be more holes in the liquid and the liquid will always become more fluid. Thus a suitable lubricant, having a viscosity of the order of a hundred times that of simple liquids, even at temperatures well above its melting point, is not obtainable from simple liquids by temperature changes. Likewise, viscosities greater than those of a simple liquid at the melting point are not obtainable by compression, for when the increase in pressure has depleted the number of holes to around 0.8 mole of holes per mole of molecules, the liquid will solidify no matter what the temperature. These considerations are consistent with Batschinski's rule that fluidity is proportional to volume.

Since in the liquid range the viscosities of simple liquids are less than 0.02 poise, while in the solid range the resistance to shear corresponds to enormously high viscosities, it is clear that intermediate viscosities are associated with the unstable intermediate volumes between liquid and solid.

(A) One interesting way to get high viscosity is to bring a substance into the liquid state without adding the number of holes necessary to melt it. This is done by adding to substance A a substance B which is soluble in the liquid but not in the solid A: this gives an entropy advantage to liquid A, so that fewer holes need be supplied to melt A, and it will therefore melt below its regular melting point. Only the few holes present will then contribute to the fluidity. This is one reason why the oils occurring in nature are useful lubricants: they are mixtures. It is to be pointed out that when two liquids mix with a net decrease in volume one expects—and finds—an increase in viscosity. This is because such a decrease occurs at the expense of the holes present.

(B) If the molecules of B are very large they may increase the viscosity of A also by reducing the fraction of space in which flow takes place [See Equation (2)].

(C) Long-chain molecules, by moving in segments, may introduce large entropies of activation to increase the viscosity. The corresponding viscosities will be relatively independent of temperature, which is an advantage in a lubricant.

(D) Hydrogen bonds, as in glycerol and certain other alcohols, produce high viscosities because these bonds must be broken in flow. However, the viscosity is strongly dependent on temperature.

(E) In certain colloidal solutions where the system approaches the gel state, flow may involve the shearing of secondary structures extending through the liquid.

Thus by taking sufficiently complicated systems one can obtain a viscosity in almost any range, and with some care the temperature coefficient can be kept reasonably low.

Boundary Friction and Boundary Lubrication

When two unlubricated surfaces are moved past each other, the ratio of the force required to maintain motion to the force pressing the surfaces together is a constant, called the coefficient of friction, or $\phi/Wg = \mu$. This law was discovered by Amontons in 1699.²⁴

The rate of motion may be treated by the method of absolute reaction rates in the following way:¹⁹

The surfaces of even optically smooth metals have irregular hills and valleys some 10^{-5} cm—500 to 1000 atom diameters—deep. In addition, the surface has smaller periodic valleys, one between each atom of the metal.²⁵ A schematic diagram of such a surface is given in Figure 5.

A second surface is pulled over the first with a velocity of the order of 1 cm sec^{-1} . Since the distance between equilibrium positions is about 10^{-8} cm , the time spent in each potential minimum is about 10^{-8} sec . The vibration frequency of an atom in a solid is about 10^{13} sec^{-1} ; therefore the atom vibrates some 10^5 times in each minimum and is able to dissipate as heat all of its activation energy. Thus the activation energy must be furnished anew for each distance λ the surfaces move relative to each other. (We shall consider later the case where the surfaces move extremely rapidly.)

FIGURE 5. The surface of a solid.

We can calculate the work ΔF^\ddagger which must be supplied for the upper surface to move to the top of a potential hill, a distance forward of $\lambda/2$. Let the upper block press down with a force Wg . The block rises an amount s due to the atomic irregularities, and the work done is Wgs . The upper block also rises an amount l due to the gross surface irregularities, and the work done is Wgl ; however, this work will be on the average positive and negative equally often, so its net effect will be small. In the third place, the moving block must overcome an energy of attraction, part of which is proportional to the weight—those bonds which are produced by plastic deformation of the surface: the work done may be written Wgr . Finally, there are work terms independent of the weight—bonds which exist when the weight is zero, non-linear terms for the elastic bonds, the work necessary to tear off surface atoms; such terms are collected into ΔF_0^\ddagger . The total work is now

$$\Delta F^\ddagger = \Delta F_0^\ddagger + Wg(s + l + r).$$

The general rate expression is

$$U = \lambda \frac{kT}{h} e^{-\Delta F^\ddagger/kT} (e^{\phi\lambda/2kT} - e^{-\phi\lambda/2kT}) \quad (25)$$

$\phi\lambda/2kT$ is an extremely large number (about 10^{16}) so the second term in parentheses is negligible. If the velocity is 1 cm sec^{-1} , λ is about 10^{-8} cm , kT/h is 6×10^{12} at room temperature; then

$$\frac{\phi\lambda}{2kT} = \frac{\Delta F^\ddagger}{kT} - 11.5 \quad (26)$$

It is seen that the term 11.5 is also negligible. The coefficient of friction is then independent of temperature:

$$\mu = \frac{\phi}{Wg} = \frac{2\Delta F^\ddagger}{\lambda Wg} = \frac{2}{\lambda} \left(\frac{\Delta F_0^\ddagger}{Wg} + s + l + r \right) \quad (27)$$

For two surfaces not actually welded together, ΔF_0^\ddagger may well be negligible. Then

$$\mu = \frac{2(s + l + r)}{\lambda} \quad (28)$$

Equation (28) shows that the important term in the coefficient of friction is $2s/\lambda$, or the ratio of the rise to the horizontal distance moved in going from the normal to the activated state. One might well surmise the actual result that μ is not very different from unity.

We now return to the problem of extremely rapid slippage. If the upper block were moved rapidly enough it could make only a few vibrations in each minimum, and so could not dissipate much of its activation energy. The system would then need to be brought only to the top of its first barrier, after which it could coast over all successive barriers. The critical speed is of the order of the speed of sound in solids, or about 5000 meters per second. A high explosive which produces a detonation wave with such a speed will demolish any material, because after the first unlocking along a shear plane the solid is torn apart extremely efficiently. The detonation velocities of several high explosives are listed in Table 4.²⁶

Table 4

| | |
|----------------------------------|----------------------|
| Mercury fulminate..... | 3920 meters per sec. |
| Nitromannite..... | 6900-7700 |
| Nitrocellulose..... | 3700-6200 |
| Picric acid..... | 7700-8200 |
| Trinitrotoluene..... | 7200 |
| Gelatin dynamite..... | 7000 |
| Ammonium nitrate explosives..... | 2700-3700 |

In contrast, if explosives are to be useful propellants, their velocity must be of the same magnitude as that of the projectile. For example, the velocity of explosion of black powder is 300 meters per second: the flame velocity in an internal combustion engine is of the same magnitude as the piston velocity (some tens of meters per second), a too rapid explosion producing "knocking," as is clearly shown in photographs of knocking and non-knocking flames in a gasoline engine.²⁷

When the two surfaces are lubricated with a monomolecular layer of primary alcohols, paraffins, carboxylic acids, or secondary alcohols the coefficient of friction is²⁸

$$\mu = \mu_0 - d - c(n - 1) \quad (29)$$

where μ_0 is the coefficient for unlubricated surfaces, d a decrease in coefficient which is characteristic of the lubricant and independent of chain length, and $c(n - 1)$ gives a decrease characteristic of the lubricant and proportional to chain length; c is independent and d almost independent of the kind of surface material. Table 5 presents some values for these parameters compiled by Adam.²⁹

Table 5

| Surface | Hydrocarbon | | | Primary Alcohol | | Secondary Alcohol | | Acid | |
|------------------------|-------------|------|-----|-----------------|-----|-------------------|-----|------|-----|
| | μ_0 | c | d | c | d | c | d | c | d |

| Alloy steel..... | .88 | .022 | .24 | .023 | .35 | | | .060 | .22 |
| Med. carbon steel.... | .83 | .022 | .23 | .023 | .33 | | | .060 | .19 |
| Nickel chrome steel... | .93 | .022 | .23 | .023 | .33 | | | .060 | .23 |
| Phosphor bronze..... | .94 | .022 | .22 | .023 | .34 | | | .060 | .24 |

A lubricant may reduce the coefficient of friction by reducing ΔF_0^\ddagger , s , l , r , or by increasing λ . The reduction independent of length, d , probably arises from a decrease in ΔF_0^\ddagger , for hydrocarbons make very poor van der Waals bonds with each other—much poorer than metal or glass. The reduction proportional to chain length probably arises as follows: In the unlubricated surfaces a large number of surface atoms “mesh,” which causes s , the mean vertical displacement of unlocking, to be large. A tightly adsorbed layer of a monatomic substance would not improve the situation. However, a longer molecule with one end tightly anchored to the surface can still orient the rest of the molecule randomly, will prevent meshing and so decrease s . Furthermore, if each additional chain atom has as much chance of hindering the meshing as did the previous chain atom, the observed linear decrease of μ with chain length would be understandable. When the hydrocarbon becomes long enough to move in segments (longer than 20-25 atoms) the coefficient will be reduced to that for the liquid, *i.e.*, approximately zero. The decrease per chain atom for short chains should also be about $\frac{1}{20}$ or $\frac{1}{25}$ of the original coefficient. The observed value is 0.023 for hydrocarbons and 0.06 for acids.

Plasticity

It is frequently stated that plastic deformation sets in at some definite value of the applied stress. While practically speaking this is about right, it is often misunderstood. It is exactly analogous to the statements that compounds start decomposing at a certain temperature or that at a definite overvoltage current starts flowing. What should be said in each of the three cases is that at a certain value of the stress, the temperature, or the applied potential the phenomenon becomes noticeable with the particular instrument one has chosen for observing the change. Progressively more accurate observations would reveal that the change sets in at progressively lower values of the disturbing influence. Thus for the velocity of a shear displacement we have already seen in Equation (14) that

$$\mu = \lambda \frac{kT}{h} e^{-\Delta F^\ddagger/kT} (e^{-\phi\lambda/2kT} - e^{-\phi\lambda/kT}) \quad (30)$$

Now if the free energy of activation for shear is large the applied force ϕ must be large before U will have a noticeable value. This insures that the second term in parentheses is negligible. But now we see that the velocity of displacement depends exponentially on the applied force ϕ , so that observable motion will set in fairly suddenly at some critical value of the applied force, ϕ_c . Because the first observable velocity U_c is only a few orders of magnitude smaller than $\lambda kT/h$, the quantity $(\Delta F^\ddagger - \phi_c \lambda/2)$ must be quite small. This insures that

$$\phi_c = \frac{2kT}{\lambda} \ln \left(\frac{U_c h}{\lambda kT} \right) + \frac{2\Delta F^\ddagger}{\lambda}$$

will depend very little (calculated on a percentage basis) upon the temperature.

The same general theory and type of treatment as that we have applied to solid friction and to plasticity lead to analogous relations for overvoltage or critical decomposition potential.

Diffusion

As was pointed out in the beginning of this article, the theory of diffusion of large particles reduces to a theory of the viscosity of the surrounding medium: so that by treating viscosity we have completed at least one phase of the diffusion problem.

The question as to what happens when the diffusing particles are of the same size as the particles of the surrounding medium still requires consideration. The

mechanism of flow within the liquid will in general be the same whether the flow neutralizes a shearing stress, a concentration gradient, or an electrical potential gradient. We have already seen that the velocity of forward motion of a particle is

$$U = \lambda k' \frac{2W}{kT} \quad (15)$$

The definition of the diffusion coefficient is $-D =$ the net number of molecules passing through a square centimeter of surface per second, divided by the concentration gradient normal to this surface, *i.e.*,

$$D = - \frac{U n_1}{dn_1/dx} \quad (31)$$

where n_1 is the number of particles, of the kind diffusing, per cc. The partial molal free energy \overline{F}_1 (or chemical potential) of a particle can be written as $\overline{F}_1 = -kT \ln a_1$, where a_1 is the activity. Then the work done in going from the normal to the activated state is

$$W = \frac{\lambda}{2} \frac{d}{dx} (-kT \ln a_1) = -\frac{\lambda}{2} kT \frac{d \ln a_1}{d \ln n_1} \frac{d \ln n_1}{dx} \quad (32)$$

Substituting Equation (32) and Equation (15) into Equation (31),

$$D = \lambda^2 k' \frac{d \ln a_1}{d \ln n_1} = \lambda^2 \frac{kT}{h} e^{-\Delta F^\ddagger/kT} \frac{d \ln a_1}{d \ln n_1} \quad (33)$$

For a perfect solution, $d \ln a_1/d \ln n_1$ is of course unity. Remembering that the equation for viscosity is

$$\eta = \frac{\lambda_1 h}{\lambda_2 \lambda_3 \lambda^2} e^{\Delta F^\ddagger/kT} \quad (18)$$

we have

$$D\eta = \frac{\lambda_1 kT}{\lambda_2 \lambda_3} \frac{d \ln a_1}{d \ln n_1} \quad (34)$$

This expression, for diffusing particles of the same size as the surrounding solvent, is to be compared with the appropriate Stokes-Einstein relation for large particles,

$$D\eta = \frac{kT}{6\pi r_2} \frac{d \ln a_1}{d \ln n_1} \quad (35)$$

Equation (34) and Equation (35) differ only by a numerical factor, which has to do with the difference in the lines of flow around small and large particles. The intermediate size range requires further investigation.

The applicability of these equations has been considered in detail elsewhere,¹⁰ so we give here only one typical example of the application of Equation (34) to the mixture of chloroform and acetone. Figure 6 illustrates the expected simplification in the curve for $D\eta$ against composition when one takes into account the imperfection of the solution by dividing by $d \ln a_1/d \ln n_1$.

If a particle is diffusing under an electrical potential as well as a chemical potential, the extra work done by the electrical field is included in the expression for W to be substituted into Equation (15). In this way one obtains all the usual equations for ionic conductance.²

High-Vacuum Distillation *

K. C. D. HICKMAN

Distillation Products, Inc., Rochester, N. Y.†

Distillation can be done at successively lower temperatures as the pressure is reduced until a limit is reached below which continued reduction makes no alteration. It is then found that if the apparatus is redesigned to dispense with the usual links between evaporator and condenser, a further lowering of temperature can be secured. Finally, a new limit is reached beyond which no device yet known will reduce the temperature of distillation. This limit is realized in apparatus called a "molecular" or "unobstructed path," high-vacuum still. Such stills, which operate best with pressures of residual gas of less than $\frac{1}{4000}$ of a millimeter, require a specialized technique of vacuum pumping. The combination of short-path still and high-vacuum pumps provides a medium for distilling labile substances with less decomposition than previously thought possible. Indeed, many substances which had been considered as fixed liquids or fixed solids have now become readily distillable. The natural fats, oils and waxes of vegetable and animal origin, many of the vitamins, the sterols, hormones, some of the simpler dyes and a large range of pharmaceutical compounds are examples.

There are so many steps in the progression from the ordinary high-vacuum still to the most efficient molecular still that the description will include some of the more useful pieces of intermediate apparatus. The steps are pictured in Figure 1 in reverse order. Here *A* represents a drop of liquid suspended freely in the center of a glass flask evacuated through the side tube *Z*. The vacuum is assumed to be so high that a molecule leaving the central drop will reach the wall without experiencing any collisions on the way. In fact, the molecule will not "know" that there are any other molecules present; its flight will be free and unobstructed. In such hypothetical apparatus, distillation will occur entirely unhindered and, therefore, at the lowest possible temperature. A practical interpretation is the small pot still *B* where the liquid rests on the bottom of a glass alembic. The bottom is warmed; part of the vapor, as shown by the cone of dotted lines, reaches the cooled ceiling where it condenses and runs out of the tube *X*. The vacuum is applied at *Y*. Such a still is only partially unobstructed since the walls condense and return to the *distilland* about half of the evaporated molecules.

Figure 1C shows a simple near approach to the unobstructed still that can be made with the minimum of glass blowing skill from an ordinary wide-necked flask. The neck should be extended considerably and at the joint a small bulb is blown which is then pushed in to form the alembic *V*. The apparatus is evacuated by side arm *W* and distillate is collected through the tube *T*. A more ambitious piece of apparatus, but one working at considerably higher pressure, is the high-vacuum refluxing still *D*. Here a large flask *S* is attached to the long neck *R* which is bent in

* "Molecular distillation," as it has been termed, gives a method for isolation of many kinds of molecules of high molecular weight, some of which approach or enter the field of colloidal dimensions, and are not easy to recover otherwise.

 D—High-vacuum fractionating still
 E—Ordinary laboratory vacuum fractionating still

From still D it is a short retrograde step to still E , which is of the type in common use in organic laboratories. A flask and fractionating column are attached by side arm N to condenser L and receiver K , manometer H and vacuum pump J . The probable pressures existing in each region during operation are as follows: M , 4 mm; N , 2 mm; L , 1 mm, and K , 0.05 mm. The progressive increase from the pump to the flask shows the resistance to the outgoing vapors which is imposed by the construction of the vessel, and it is an illustration of the advantage of using apparatus ap-

proximating the simpler diagram *A* when the lowest temperature distillation is required. However, it should be realized that still *E* gives considerable fractionation and therefore has a separating power of more than one theoretical plate. Under ordinary conditions, when it is operated at perhaps 10-millimeter boiler pressure, a separation equal to 3 or 4 theoretical plates may be secured. Even with complicated distilling columns, separation comparable with stills of the Podbielniak type is seldom reached. All the stills *D*, *C*, and *B*, provide fractionation in lesser degree, even still *B* returning about half the distillate for redistillation. This demonstrates that short-path distillation is undertaken at the expense of sharpness of separation and there is, therefore, every reason *not* to use a short-path still except when the perishability of the substance under treatment makes it necessary.

FIGURE 2. Molecular pot still with pumps, trap, and high-vacuum gauges.

Before proceeding with a detailed development of the subject, it is considered best to familiarize the reader with the general appearance and technique of the unobstructed-path distillation assembly. In Figure 2 the pot still shown on the right is fitted with a detachable re-entrant cover and connections to the receiver for distillate and to a high-vacuum gauge. This is conveniently a Pirani hot-wire instrument, the indications of which are shown in the left-hand meter of the right-hand box. Material to be distilled is placed in the flask and warmed by a small electric heater. It is convenient if a shallow beaker of castor oil is interposed between the flask and heater to keep the temperature uniform and the walls warm. Between the flask and the high-vacuum pump is placed a solvent trap which may have a vacuum-jacketed base to retain without serious re-evaporation any liquid which condenses at the temperature of the Dry Ice or other refrigerant used. The condensation pump

need not be an elaborate piece of apparatus, a single-stage pump filled with butyl phthalate or Octoil being adequate if the tubes between the still, trap and pump are sufficiently wide. The condensation pump in turn is attached by a wide tube to a mechanical pump which should have an effective operating capacity of 100-500 cc per second at 0.08 mm of mercury (the pressure is measured by the gauge on the left). It is more important that the mechanical pump shall have adequate volumetric capacity than reach very low pressure. Accordingly, if the choice is to be made between a single- and a double-stage oil-immersed pump of approximately the

FIGURE 3. High-vacuum pot still assembly.

same cost, the former should be chosen, but should be supplied frequently with fresh oil. The higher volumetric capacity will enable the apparatus to be brought under vacuum quickly.

To operate the apparatus, the material is placed in the alembic or still and is warmed gently to melt or reduce its viscosity. Vacuum is applied cautiously by operating the mechanical pump intermittently, and in this way the material can be carried through the eruptive part of the degassing treatment without seriously splashing the lid of the alembic. Should such splashing be troublesome, air may be admitted momentarily, the detachable lid removed and cleaned, and the apparatus again brought under vacuum. The second degassing will not be as violent as the first if the change is made rapidly.

A useful compromise, according to the scheme C in Figure 1, is shown in greater detail in Figure 3. Here the material to be distilled is held in a wide-necked flask with a low alembic on the neck. Another alembic much higher up is used for catching stray volatile materials. The whole of the neck of the flask is cooled by air

blast. A clean mercury manometer is attached directly to one side of the apparatus, while the other side is connected through a Dry Ice trap to the vacuum pump. Stirring of the contents is induced by a small pin point flame. Such apparatus will give very satisfactory separation of many materials which otherwise could only be distilled in the molecular pot still.

Historical

The researches that have led up to the modern highly specialized industrial or research-type molecular stills are buried in obscurity, but Detwiler¹ has discovered some early references.² Perhaps the first scientific analysis of short-path distillation conditions was made by Brönsted and von Hevesy³ during their work on the separation of the isotopes of mercury. In the early 1920's Waterman⁴ and collaborators in Holland made many experimental low-temperature distillations using semi-unobstructed-path apparatus. In the same decade, C. R. Burch built an unobstructed-path tray⁵ still which he attached to the newly invented Langmuir condensation pump.⁶ He was able to separate out from "undistillable" Vaseline a number of comparatively fluid oils of extremely low volatility. These materials had many interesting properties and could be used, for instance, to replace mercury in the condensation pump where they produced in one step extremely low pressures of the order of 10^{-5} , 10^{-6} mm without the interposition of a cooled trap. Burch's laboratory experiments were transmuted into a self-contained industrial technique which was set forth in British⁷ and other patents.⁸

Experiments similar to Burch's and Waterman's were started in other places, notably the Bureau of Standards at Washington, D. C., by Washburn⁹ *et al.*, and at the Kodak Research Laboratories¹⁰ in Rochester.

Improvements in the Molecular Still

It was soon apparent that there are two interrelated factors influencing thermal decomposition of a labile substance: temperature and time. There is an indirect factor—viscosity—which has a marked effect, since with substances of high molecular weight such as are generally treated in the molecular still there is very poor stirring of the distilland, and the distilling surface becomes impoverished and no longer represents the composition of the main body of the liquid. These factors—temperature, time and viscosity—make it desirable to operate with very thin films of distilland. Burch and Bancroft⁸ devised tray stills in which the distilland wandered from one tray to another, thus providing a thin layer under moderate turbulence. A more important development and one which has been universally adopted is the falling-film still.^{11, 12} Here the distilland is distributed around the sides of a vertical cylinder down which it flows in a fairly uniform stream, the uniformity depending on the exactness with which the liquid is distributed on the top of the column, on the cleanliness of the column, its orientation and on surface tension changes occurring during distillation. The falling-film column is maintained at high temperature and is housed within a cooled cylindrical condenser; the space between the column and condenser is evacuated so highly that the evaporating molecules meet no obstructing particles on their journey to the condenser.

A diagram of a laboratory falling-film still is shown in Figure 4. The distilland is held in the reservoir *A* and is admitted through a drip feed or sight glass *B* through an adjustable stopcock to the preheating tube *C*. It emerges into the "explosion" bulb *D*, where much of the dissolved gases and vapors are given off to be drawn away by a small auxiliary vacuum pump. The partially degassed liquid runs down a wide spiral tube *F* where the temperature is increased and more gas is drawn away to the main vacuum pump. The liquid then passes on to the hot falling-film column *H*, which may have a plain surface or an embossed pattern, or may be given a ground-glass finish as suggested by Markley¹³ and Detwiler. The column is

housed within the condenser *K*, evacuated by means of a condensation pump *G*. The distillate collects in the small flask to the right, and residue passes to reservoir *L*. The column *H* may be warmed by electrical winding or by the circulation of hot fluid. In the present case it is warmed by vapor supplied by the flask at the base of the picture. This apparatus shows no vacuum meter other than the McLeod gauge attached to the trap. Various laboratory falling-film stills have been described by Waterman,⁴ Markley,¹³ and others. The control board and one of the distillation units in a larger industrial falling-film still¹⁵ is shown in Figure 5. This happens to

FIGURE 4. Laboratory falling-film still.

be the fifth and last unit in a series of stills each unit of which accommodates 200 gallons of oil per day. The metal column has a finely embossed pattern for distributing the distilland and is covered by a bell jar. The vacuum is applied at the base which also serves as a support. Very wide ducts and condensing channels are provided so that there shall be little obstruction to the residual gas which emerges.

Centrifugal Still

The duration of distillation, which was 1-2 hours in the pot still, was reduced to about 10 minutes and 30 seconds in the industrial and laboratory falling-film stills, respectively. There remained much room for improvement both in evenness of distribution and time of exposure of the distilland. Both factors have been improved

FIGURE 5. Fifth unit and controls of a commercial molecular still installation. The falling-film still is seen under the bell jar to the left, and the thermometers and heat controls to the right.

FIGURE 6. Sectional elevation of a centrifugal molecular still.

in a still fitted with a rotating distilling surface.¹⁶ A diagram of the centrifugal still is shown in Figure 6, which presents a section in elevation. The apparatus is mounted on a metal base plate, shown as the vertical crosshatched portion which carries a bearing and stuffing box through which the shaft of a conical rotor projects. The shaft and rotor are driven by a motor shown to the right. The distilland is applied to the center of the rotor whence it is flung outward to the water-cooled collecting gutter and passes away from the still through the residue pipe. A radiant

FIGURE 7. A five-plate centrifugal molecular still used in commercial production of vitamin E.

heater and succession of reflectors are situated behind the rotor. The condenser stands in front of the rotor and the entire assembly is housed by a glass bell jar. In apparatus of this type the time of exposure of the distilland is reduced to 0.2-0.1 second and it becomes possible to distill many substances which would literally explode if heated for a longer period. The industrial interpretation of the centrifugal still is shown in Figure 7, and a laboratory cyclic variety in Figure 8.

Cyclic Distillation; The Elimination Curve

The chemist trained to rely on the interrelation of temperature and pressure may find himself somewhat at a loss when first performing a molecular distillation. There is no pressure conveniently measurable in the still, and distillation takes place at any difference of temperature between evaporator and condenser, the rate varying with the conditions. The operator thus has little to guide him in the selection of distillates.

Again, the separation, generally less than one theoretical plate, is so poor judged by his previous standards that he is distressed to find a little of every component in each sample of distillate. The distillates differ among themselves merely in relative concentration of the components. It is these difficulties which have caused the valuable properties of the molecular still to be neglected in so many organic laboratories.

A system of molecular distillation is required which will provide a substitute for the ordinary boiling-point measurement. Such a system has been provided by the technique of the "elimination curve" introduced by Embree¹⁷ and Hickman.¹⁸ Cumbersome and laborious, the method nevertheless gives the required information and provides a systematic way of comparing molecular distillations done in different apparatus under varying pressures of residual gas.

FIGURE 8. A cyclic centrifugal single-plate molecular still of semi-commercial proportions.

The method requires the withdrawal of a large number of distillate fractions over equal periods of time, the temperature of the distilland being raised a constant amount whenever the receiver is changed. The exact technique for this procedure has been detailed elsewhere.¹⁵ In brief, the material to be distilled is dissolved in a specially prepared mixture of "constant yield" and "residue" oils. These can be made from glyceride or petroleum raw materials. Where biological substances are under investigation the glycerides are preferable because of their digestibility and the ease with which they can be removed by saponification. A typical distillation required 200 cc of such a mixture which is cycled for 5- or 10-minute intervals with temperature increments of 5 or 10°. Some 15 to 30 fractions will be withdrawn between the limits of 80 and 250°; these are now examined for all the constituents of interest. It will be found that the concentration of a simple substance will always vary from one fraction to another according to the elimination curve of Figure 9. The reason for

this has been exhaustively presented by Embree.¹⁷ The curve has the fundamental quality of being dependent upon arithmetic and not upon the chemical nature of the substance. However, the curve can be distorted by chemical changes occurring during distillation so that the shape of the curve is a very sensitive indicator of the state of the molecule.

The curve has a maximum which can be used conveniently as a boiling point. In Figure 9 the main curve has a maximum at 125°. Every time the material is distilled under these conditions this substance will collect in maximum yield at 125°.

FIGURE 9. Typical elimination curves.

Unfortunately, if the distillation operation is quickened or slowed or performed in apparatus of different design, the curve will shift along the temperature axis. The maximum is, therefore, not an absolute analog of boiling point. It has been found that a series of substances, distilling from the same kind of constant yield and residue oil, generally provide maxima in the same order and it is, therefore, only necessary to include an easily recognizable pilot substance, such as a brightly colored dye, to be able to fix the maximum of the experimental substance. In this way a fairly reliable series of relative evaporation temperatures can be assembled; and it is possible to follow the concentration, changes of properties and general chemistry of many substances by molecular distillation with the same order of exactness that can be derived from other well-known physicochemical measurements.

The technique has been applied as a routine matter in the laboratories of Distillation Products, Inc. during the past five years. The elimination curve is, of course, only a glorified distillation curve and such curves have been known since the beginnings of chemistry. Its importance in the present connection is that it provides a conventionalized method of picturing the behavior of substances in the molecular still. The operator who has been provided with the elimination curves of a mixture of substances can separate them by distillation with the least trouble.

Applications of the method outside of this laboratory have been slow to appear in the literature. A notable exception is the elimination curve of tocopherol presented by Steenbock, Quackenbush, *et al.*¹⁹ Illustrations of the method must thus be taken from our own work dealing with the oil-soluble vitamins.

We shall consider the constituents of a fish-liver oil. As a first step, the oil is saponified and mixed with constant-yield and residue oils, adding a few parts to the million of the pilot dye celanthrene red. The mixture is placed in the cyclic falling-film still and separated into about 20 fractions. The relative concentration of celanthrene red in the fractions is determined by colorimeter and the concentration of vitamin A and cyclized vitamin A by the ultraviolet spectrograph. The extinction coefficients are multiplied by the volume of the fractions, and the total relative yield per fraction is plotted against temperature, giving the three curves of Figure 9 which differ in height and position on the temperature axis but are approximately similar in shape. The curves correspond to vitamin A-alcohol, anhydro vitamin A and celanthrene red. Their relative elimination maxima or boiling points are as follows:

| Substance | Relative Elimination Maxima ($^{\circ}$ C) |
|------------------------|--|
| Vitamin A-alcohol..... | 126 |
| Anhydro Vitamin A..... | 108 |
| Celanthrene Red..... | 127 |

If the distillation had been done on a fish-liver oil without the intervening saponification, a different set of curves would have been obtained. Thus if the fractions had been examined for vitamins A and D, the former by ultraviolet or antimony trichloride tests, the latter by animal assay, very small quantities of the vitamins would have been found in the low-boiling fractions, while large quantities would have appeared at higher temperatures. But in no case would a pure elimination curve have been obtained. The reason for this is that the vitamin A occurs naturally esterified with fatty acids selected from the fat of the animal from which the vitamin A is recovered. The same applies to vitamin D, but as there is more than one sub-

FIGURE 10. Elimination diagram of important constituents of a fish-liver oil.

stance with vitamin D activity, a great many different esters occur. In the common fish-liver oils the C_{10} , C_{18} and C_{22} esters predominate.

The more important constituents of an oil, as revealed by the elimination technique, are shown in Figure 10. The relative heights of the curves are weighted arbitrarily by psychological standards. The vitamin A and glyceride fat curves are accorded first importance, followed by the preservative-tocopherol curve and the odor and fatty acid curves. While the quantity of material contributing to odor is small its importance can not be overestimated in practical nutrition. Figure 10 is more than an illustrative map since it indicates the way in which commercial vitamin A distillate is made from a fish oil and shows why this method of manufacture has come into general use. The oil requires little but a simple passage through the molecular still to strip out the unwanted volatile materials and then to separate the vitamins unharmed and in their natural ester forms. The remaining oil passes unaltered from the stills and becomes available for other edible or industrial purposes. The vitamin A esters together with the tocopherols provide a relatively stable mixture suitable for medicine and food fortification.

It is not the purpose of this paper to lay too much stress on the elimination method. This is a *tour de force* which provides more information than it does practical separation of constituents. The information must always be applied afterward in some other way, either by guiding distillations done without constant yield of residue oils, or indicating some other method of purification.

Applications of the Molecular Still

Soon after Burch's inventions in high-vacuum distillation, it became apparent to chemists that a revolution was impending in fat technology. This revolution, however, did not come about because the method was inexact, and it was extravagant in apparatus, vacuum requirements and the energy consumed in distillation. The hot evaporator is held opposite and near to the cold condenser so that 5 to 10 times as much heat is used in prewarming the oil and keeping it hot as is actually employed in distillation.

Industrial stills at this time of writing are used almost exclusively for the production of oil-soluble vitamins. Vitamin A is concentrated from low-grade, low-potency fish-liver oils which are otherwise unsuitable for human consumption. Vitamin E similarly is distilled from crude or inedible vegetable products.

Some Theoretical Considerations

This review has stressed the practical nature of molecular distillation, it being assumed that the reader who wishes to study the subject more intimately will refer to the original literature. For this reason the technique of high-vacuum pumps and peculiarities of measuring gauges have not been related. It is desirable, however, to include some quantitative figures on the kind²⁰ and rate²¹ of distillation to be expected in the molecular still.

Under molecular conditions and direct transfer to the condenser, molecules do not re-enter the distilland, and there is no equilibrium between liquid and vapor. The quantity distilling is proportional to $P\sqrt{T/M}$. The relative quantities of two or more constituents distilling at a given temperature are:

$$\frac{p_1}{\sqrt{m_1}}, \frac{p_2}{\sqrt{m_2}}, \dots, \frac{p_n}{\sqrt{m_n}}$$

In ordinary distillation where the rate of escape of vapor is less than the rate of generation, molecules re-enter the surface and produce approximate equilibrium between vapor and liquid phases. The quantities of constituents distilling are then proportional to their partial pressures p_1, p_2, \dots, p_n . Molecular distillation will

thus effect separation between substances of equal vapor pressure, providing that molecular weights are different. On the other hand, substances having $p_1/m_1 = p_2/m_2$ which are inseparable molecularly can be separated if the molecular still is abandoned and one of the partially obstructed-path alembics is used instead.

The actual mass, W , in grams of a constituent evaporating per second, per centimeter squared, of substances of molecular weight, M , at absolute temperature, T , at evaporating pressure, P millimeters or p microns of mercury is:

$$W = 5.83 \times 10^{-2} \times P \times \sqrt{M/T}$$

and

$$p = \frac{17,200 \times W}{\text{cm}^2} \times \sqrt{T/M}$$

Now it so happens that the factor $\sqrt{T/M}$ approaches unity; it also happens that the molecular weight rises hand in hand with temperature of distillation, so that the substances in the range accommodated by the molecular still have an almost constant rate of distillation—a factor of about 33 per cent, accounting for all likely variations. We may thus assemble the following list of useful distillation rates:

One square meter of evaporating surface will distill per second, at a saturation pressure of 1 μ : 0.5 gram of stearic or palmitic acid, or; 0.55 gram of sterols, or; 0.75 gram of a typical glyceride fat.

Bearing this simple relation in mind, the rate of distillation can be adjusted in a small still so that it will occur under approximately molecular conditions.

References and Acknowledgements

The author wishes to acknowledge a debt of gratitude to his colleagues at Distillation Products who have placed their work so fully at his disposal. Much of the material quoted from the general literature has been traced through "review articles," important among which are the two bibliographies of Detwiler,^{1, 22} the symposium articles by Burch,²⁰ Fawcett,²¹ Burrows,²³ Phipps and Meade²⁴ and Waterman.⁴ A recent compilation from the pen of D. D. Howat has appeared in the Chemical Age.²⁵ The reader is referred to these and original papers for further details. Not mentioned in this short review are the important researches of Knudsen on gaseous flow through tubes and orifices. The reader is referred to a small monograph by Knudsen²⁶ and to the standard works on high-vacuum technique such as those by Dushman,²⁷ Dunnoyer²⁸ and Strong.²⁹

States of Aggregation of Some Paraffin Chain Compounds

ROBERT D. VOLD

Assistant Professor of Chemistry

and

MARJORIE J. VOLD

Research Associate in Chemistry, University of Southern California

Paraffin chain compounds are remarkable for the number and variety of crystalline and mesomorphic forms they exhibit. Thus the *n*-paraffin hydrocarbons (I) furnish examples of three different crystal forms and one probably mesomorphic modification. For the *n*-fatty acids (II) there are three and perhaps four crystal forms; for the alcohols (IV), two; for the esters (III) one or more crystal forms and also a mesomorphic form; and for the simple triglycerides (III) one crystal form, and two probably mesomorphic forms. Sodium salts of the *n*-fatty acids (VI) display probably three alternative crystal forms, as well as a sequence of at least as many as five stable mesomorphic forms.* The purpose of this paper is to correlate the known experimental facts concerning these states with various hypotheses that have been advanced concerning their structure and stability.

It is desirable at the outset to distinguish between real differences in polymorphic form (*i.e.*, discrete phases) and other variations in the condition of matter in which degree of dispersion, protective colloids or other special circumstances have profoundly modified the physical properties of a substance without any fundamental alteration in the packing together or manner of arrangement of its molecules.

It is not at present possible to specify how extensive an alteration in molecular arrangement is required to produce a phase change. For example, a liquid is thought of as containing a high degree of "local order," the distribution over a few molecular diameters about many single molecules being, at any instant, similar to that found in the crystal. Although at high temperatures the number and persistence of such groups are much less than at temperatures just above the freezing point of the substance, the corresponding variation in measurable properties is continuous. However, a definite discontinuity in primary physical properties, such as volume or heat content, accompanies the transformation: nematic liquid crystal—isotropic liquid; this transformation is still regarded as consisting only in a variation in the number and persistence of groups of oriented molecules, although here a genuine phase change has occurred.

Similarly, glasses are sometimes thought of as a separate state, and sometimes as

* The total number of forms that can be realized for sodium stearate now totals probably ten. Of these, two are certainly liquid crystalline and three crystalline. However, positive classification of the remaining forms into one category or the other requires further experimental work or may even remain indefinitely a matter of definition.

undercooled liquids, there being no satisfactory theoretical criterion for their classification. The unstable γ form of simple triglycerides, obtainable by rapidly chilling the liquid, is possibly an example of an anisotropic glass.²⁵ Parallelism of the paraffin chains seems to be achieved, but not regular arrangement of their ends in planes by the time the thermal energy becomes too low to allow the molecules sufficient mobility to complete the process of crystallization.

The best criterion for characterizing a given variant on the spatial distribution of molecules as a separate form or phase is the experimental one of the detection of transitions. Most of the discussion in this paper is concerned with modifications of paraffin chain compounds which are separate phases in this sense. The problem is to try to account for the very large number of forms, and to relate changes in behavior to the internal structure of the phase and to the physical constitution (*i.e.*, anisometry, heteropolar character, etc.) of the molecules.

Crystal Forms of Paraffin Chain Compounds

Crystal forms of paraffin chain compounds fall into two main categories, rhombic and monoclinic. In the rhombic form the axis of the zig-zag chains lies perpendicular to the planes containing the terminal groups. As many as four monoclinic forms of one compound have been reported. These differ from one another principally in the angle of inclination of the chain axis to the terminal planes.

Not all paraffin chain compounds have been obtained in the rhombic form. Examples are the fatty acids and the methyl esters of an odd number of carbon atoms. The α form of the ethyl esters, although the chains are perpendicular to the terminal planes, is possibly not fully crystalline. Potassium acid soaps¹³ and lead soaps³⁵ ordinarily crystallize in the rhombic form. The non-appearance of a rhombic form is associated with strong attractive forces between the terminal groups, leading to their closer packing. Thus for the hydrocarbons,⁶ when the monoclinic lattice is strained by addition of homologous impurities, whose different chain length prohibits efficient packing of the heads, transformation occurs to the rhombic form.

Figure 1 shows the c spacing (separation of the planes containing the terminal groups) for the rhombic form of several series of paraffin chain molecules. It is at once apparent that there are two series of such compounds. In one series successive molecules are oppositely oriented, so that the lattice unit is a linear double molecule of a total length similar to that of the true compounds, such as the lead soaps or potassium acid soaps. This condition does not occur in the hydrocarbons (since the molecules are symmetrical), nor in ketones other than methyl ketones, nor in ethyl esters. Methyl esters of an even number of carbon atoms behave like ethyl esters. The odd ones crystallize as double molecules, but not in the rhombic system.

For both series the increment in c spacing is very nearly 1.27 Å per CH₂ group, as is required for a plane zig-zag carbon chain with tetrahedral bond angles and the normal C-C bond distance.

Schoon¹⁸ has given an excellent discussion of the concept that the various monoclinic forms may be considered as derivable from the rhombic lattice by means of a sort of shear along some definite plane. The amount of the displacement is "quantized," being some multiple of 1.27 Å in order to maintain an efficient packing of the chains. Moreover, in all forms the short spacings must be such that each molecule has about the same apparent cross-section perpendicular to its axis, since the van der Waal's forces between the chains have not been altered in the shift. Thus, for a shear parallel to the b - c plane ($[100]$), one has the two relations,

$$\tan (90 - \beta) = 1.27 \, n/a_0$$

$$a_n = a_0/\sin \beta$$

where n is an integer giving the relative displacement of the chains in number of methylene groups, β is the monoclinic angle, and a_n one of the principal axes of the new crystal. These relations can be seen from Figure 2, taken from Schoon's paper.

Fig. 1 *c* Spacings of the Rhombic Form of Several Series of Paraffin Chain Compounds

FIGURE 1. *c* Spacings of the Rhombic Form of Several Series of Paraffin Chain Compounds. A, sodium soaps; B, lead soaps; C, simple triglycerides; D, potassium acid soaps; E, methyl ketones; F, aliphatic alcohols; G, methyl esters (Even no. of C atoms); H, ethyl esters; J, ketones other than methyl ketones; K, hydrocarbons.

The *b* spacing remains constant. The *c* spacing is $c_0 \sin \beta$, owing to the tilt of the chains, and the *a* spacing varies to keep $ab \sin \beta$ constant. A second possible series of monoclinic forms results from a shear along the *a-c* planes ([010]), *a* and *b* spacings and the values of β for these hypothetical structures are shown in Table 1.

The monoclinic forms derivable by this means differ from one another in the magnitude of the monoclinic angle β between the chain axis and the terminal planes, and also in the values of the *a* spacing. One series has $b = 7.47 \text{ \AA}$ and the other has $b = 4.97 \text{ \AA}$. When the *c* spacings have been determined for a homologous series, β can be determined from the increment per CH_2 group, which is $1.27 \sin \beta$. This

fact assists in a tentative classification of the observed results according to Schoon's scheme even where the a and b spacings have not been determined.

Where there are several polymorphic crystal forms for a series of paraffin chain compounds it has become conventional to designate the rhombic form by the symbol A or α , and the monoclinic forms by the symbols B (β), C, D, etc., in the order of decreasing c spacing. Occasionally, as for the fatty acids,¹³ the symbol A has been

FIGURE 2. Alternative Methods of Packing of Hydrocarbon Chains:
 $a = a_0 / \sin \beta$; $b = b_0$; $c = c_0 \sin \beta$. [After Schoon, T., *Z. physik. Chem.*,
 B39, 385 (1938).]

used for the monoclinic form of longest c spacing when a rhombic form does not exist. The situation is confused by the use of the same symbols to designate forms with similar temperature regions of stability without regard to structure, as in the case of the α form of the ethyl and methyl esters of n -fatty acids. Schoon's system, given in Table 1, seems more rational, though it is admittedly cumbersome and, in addition, presupposes that all crystal forms of these compounds can be so classified.

Table 1. Characteristics of Monoclinic forms of Paraffin Chain Compounds derived by Distortion of the Rhombic Lattice.

| 1. Displacement parallel to [100] | | | |
|-----------------------------------|-------|------|---------|
| symbol | a | b | β |
| β_1 | 5.135 | 7.47 | 75° 15' |
| γ_1 | 5.575 | 7.47 | 62° 58' |
| δ_1 | 6.26 | 7.47 | 52° 30' |
| ϵ_1 | 7.105 | 7.47 | 44° 20' |
| 2. Displacement parallel to [010] | | | |
| β_2 | 7.58 | 4.97 | 80° 19' |
| γ_2 | 7.88 | 4.97 | 71° 13' |
| δ_2 | 8.38 | 4.97 | 62° 57' |
| ϵ_2 | 9.04 | 4.97 | 55° 50' |

Although only one of several crystal forms of a given compound can be stable at a given temperature, different ones can be obtained in a metastable condition by suitable experimental procedures, and persist indefinitely. For example, sodium stearate at room temperature can be either rhombic or monoclinic.⁴⁰ Piper⁸ finds that films of palmitic acid melted onto glass show the C form, while pressed films give a mixture of A and C forms. Similar results obtain for other fatty acids.

Differences in c spacing of up to 0.7 Å may occur within the same crystal form prepared in different ways, because of distortion of the lattice.

Progress in the elucidation of the structure of the crystal forms of paraffin compounds was given a great impetus by the painstaking preparation of highly purified materials. This is particularly significant for x-ray work, where conclusions

are based on the quantitative as well as the qualitative features of the diffraction pattern. Sometimes^{15, 16} homologous impurities form solid solutions with the material under investigation and give rise to changes in the lattice constants roughly proportional to the amount present. Sometimes, as for solutions of hydrocarbons C_{20} or C_{26} in C_{28} , the qualitative behavior is altered. In this instance⁶ C_{28} normally occurs in the C monoclinic form, but with additions of 10 per cent of C_{26} or only 2.5 per cent of C_{20} , transformation to the rhombic (A) form occurs.

In the following summary of the reported crystal forms of various paraffin chain compounds, an effort has been made at classification according to the Schoon system. When a and b spacings and the value of β are available, they show immediately to which of Schoon's classes, if any, the substance belongs. When only a value of β calculated from the increment in c spacing is available, the assignment is not so definite, γ_1 , and δ_2 , for example, being indistinguishable.

Hydrocarbons of less than 26 carbon atoms apparently crystallize in form γ_1 , (B) while those of more than 26 carbon atoms give form δ_1 , (C) judging from the increments per methylene group in the c spacing. The alcohols commonly crystallize in the rhombic form (α) but have also a monoclinic type (β) which appears to correspond to Schoon's category ϵ_2 . The methyl esters (β) belong to class γ_1 . Here there are two series with slightly different c spacing, one for the odd and one for the even members. Alternation of this kind does not occur for the rhombic forms, and not universally for monoclinic forms. The β form of the ethyl esters is also γ_1 , but the lattice unit is a single molecule rather than an oppositely oriented pair, as is the case for the methyl series. The β form of the simple triglycerides has the same monoclinic angle as the ethyl esters, but its crystal structure is probably more complex than that of the esters of monohydric alcohols. The behavior of the fatty acids is very complex. Plots of c spacing against the number of carbon atoms in the acid¹⁸ show seven straight lines, 3 for the even series and four for the odd series. The slopes for the even series correspond closely to that expected for forms $\gamma_2(A)$, $\gamma_1(B)$ and $\epsilon_2(C)$ respectively. The B and C forms for the odd series have nearly the same increment in c spacing per methylene group, and therefore do not fit into the scheme of Table 2. The a and b spacings for β -margaric acid have been determined.¹⁸ Apparently its structure differs from that being here assumed, since the cross-section, $ab \sin \beta$, is larger (39.6\AA^2) than the fairly constant value of 37.0 for other paraffin chain compounds; also the b spacing is very small (4.63\AA , compared to 4.97). Potassium soaps³⁴ have a quite small increment in c per CH_2 group, putting them possibly into class ϵ_2 or δ_1 . The monoclinic form of sodium soaps studied by Thiessen and Stauff⁴⁰ does not seem to fit the Schoon system.*

Although the apparent cross-section area of the paraffin chain remains nearly constant from crystal to crystal ($ab \sin \beta = 37\text{\AA}^2$), the field of force about the axis of the chain cannot be considered to have cylindrical symmetry. Thus Muller⁵ finds that the thermal expansion along the a axis for the rhombic form of the hydrocarbons is about 7 per cent between liquid-air temperatures and the melting point, while that along the b axis is only about 2 per cent. (Expansion along the c axis is negligible). As the temperature is raised, oscillations about the chain axis increase in amplitude despite the lack of symmetry of the field of force, until at a sufficiently high temperature free rotation occurs, as in the case of ethyl stearate.³⁰ Ethyl undecylate, on the other hand, melts at a temperature too low for the molecules to have sufficient rotational energy to overcome the crystal forces opposing rotation.

* According to J. W. McBain and A. de Bretteville, Thiessen and Stauff's paper contains many numerical errors which probably vitiate any conclusions drawn from it concerning the structure of the monoclinic form.

Liquid Structure of Paraffin Chain Compounds

The transformation of a paraffin chain compound from the crystalline to the liquid state consists, as for other crystals, in the disappearance of long-range order. The overall distribution of molecules relative to one another is random, but there still exist transient groupings of small numbers of molecules with the same arrangement as in the crystal.

To this concept must be added, for paraffin chain compounds, the consideration that the chains can become coiled in the liquid state. Thus, Kauzmann and Eyring⁴⁸ find from viscosity measurements that not more than an average of 14 methylene groups can maintain themselves in an extended plane zig-zag arrangement for any appreciable time. Meyer and Lühdemann,⁴⁹ on the basis of osmotic pressure measurements in fairly concentrated solutions, suggest a kinetically active unit of 17 carbon atoms. Similarly, Huggins,⁵⁰ in calculating the entropy of liquid paraffin hydrocarbons (which he finds to be a linear function of the number of carbon atoms at any one temperature), considers that the chains are kinked in a completely random manner, or perhaps even sufficiently coiled up to give essentially spherical molecules. Hildebrand⁵¹ has ascribed the nearly ideal behavior of solutions of paraffins, even of quite different chain length, to the fact that the molecules lie parallel, two short ones end to end not acting very differently from one longer one. The occurrence of nearly ideal solutions, however, does not necessitate a parallel arrangement of extended chains if the coiled structure is regarded as changing continuously with thermal agitation, rather than being rigid. X-ray evidence^{47, 52, 58, 59, 60} shows, on the other hand, that adjacent molecules are on the average roughly parallel and, further, that for molecules of up to ten carbon atoms, the chains are essentially straight.

The Melting Process and Mesomorphic Forms

The transformation of a substance from crystal to liquid is often thought of as occurring sharply at a single temperature which has come to be known as the melting "point." Though justified in many cases by laboratory experience, the concept of a melting point has proved difficult to incorporate into statistical theories of the solid and liquid states. Molecules are held in position on a lattice by mutual attractions and repulsions. As the temperature is raised they oscillate about these positions with ever-increasing amplitude and anharmonicity; finally the "vibration" is replaced by translatory movement, all semblance of gross crystallinity (long-distance order) disappears, and the substance is said to have melted. A definite amount of energy is required for a given molecule to break loose from the forces binding it to its equilibrium position, and the proportion of molecules having sufficient energy for this scission increases with increasing temperature. What is required of theory is an explanation of why the proportion of free molecules increases so tremendously over a temperature interval sufficiently narrow to give rise to melting phenomena at all (cf. ref. 53, p. 103).

In presenting their ingenious work on the melting behavior of paraffin chain ketones and their mixtures, Oldham and Ubbelohde³³ discuss the hypothesis of "coöperative lattice flaws." According to this theory, when one imperfection develops in a lattice, the energy required to loosen adjacent molecules diminishes; when two imperfections develop close together they exert much more than a double effect in diminishing the energy required to loosen intervening molecules; finally a network of such coupled lattice defects reduces the remaining energy requirement for complete catastrophic breakdown of the crystal to a negligible value, so that melting occurs.

In a heteropolar molecule, such as, for example, palmitic acid, the constraints operating to maintain the terminal—COOH groups in place must be quite different, in

both degree and kind, from those operating on centrally located methylene groups. The existence of a sharp melting point must here be due to a further coupling, whereby a network of defects or flaws in the hydrocarbon part of the lattice reduces the energy required to destroy the more rigid framework of the carboxyl groups so that complete disruption can occur at one temperature.

However, there are cases where interaction between groups of different polar character is not very strong, so that breakdown of the crystal lattice does occur in steps. Bernal and Crowfoot⁵⁴ have summarized the structural requirements for the occurrence of liquid crystalline or mesomorphic phases: namely, (1) rod-like or plate-like geometric form, (2) heteropolar character, but with the polar group not too strongly polar. Classic examples of mesomorphism are the nematic liquid crystalline phase of *p*-azoxyanisole and the smectic liquid crystalline form of ethyl *p*-azoxybenzoate. These, and others of the same type, have been described by many authors.⁵³ Sodium salts of the *n*-fatty acids constitute the most outstanding example of this kind of behavior yet reported, there being at least five, and perhaps more, different intermediate forms of the same substance, each with its own definite temperature range of stability.

The step-wise breakdown of some paraffin chain lattices offers the opportunity to achieve a detailed understanding of the mechanism of the melting process, when the structure of each of the intermediate forms has been determined. At present, however, only scattered fragments of information are available.

The development of free rotation about the chain axis could be considered as a step in the melting process. Baker and Smyth⁵⁵ advance the idea that many compounds in which the entropy of fusion is abnormally small can be considered to have developed degrees of freedom, over a range of temperature preceding the melting point, which are usually acquired only during melting. The idea is that when the substance can increase its entropy through such means with only a very small change in free energy, actual melting can be economically postponed to a higher temperature. Such compounds have therefore abnormally high melting points, or alternatively, abnormally short temperature ranges of stability of the liquid phase. This phenomenon is found most strikingly for molecules of nearly spherical shape where three-dimensional rotation is possible; thus it is pronounced for tertiary butyl bromide, less so for isopropyl bromide, and absent for *n*-amyl bromide.

The normal paraffin chain hydrocarbons⁵ undergo a transformation near their melting points which can be regarded as a step toward melting involving even less rearrangement than the development of rotational freedom. It follows from the plane zig-zag structure of the hydrocarbon molecule that the plane through the methylene groups of a single molecule can assume various orientations, *i.e.*, the molecules are lath-shaped rather than rod-shaped. On the rhombic crystal form the chains are oriented so that these planes are perpendicular to each other along the diagonal of the *ab* crystal face, as shown in Figure 3a. Just below the melting point transformation occurs to the layer structure shown in Figure 3b. This is revealed experimentally by the disappearance of lines in the x-ray diffraction pattern coming from the [200] planes.

Methyl and ethyl esters of fatty acids separate a transparent form (α) on cooling the liquid. For esters of odd acids this form undergoes a reversible transition to a monoclinic structure (β); for the even acids this transition is monotropic. Except for methyl esters of odd acids, the α form has the chain axis perpendicular to the planes of the terminal groups. There is only a single lateral spacing indicating a mean distance of closest approach of the parallel paraffin chains of about 4.2 Å. Perhaps the planes of the individual molecules are here randomly oriented. This structure can be considered to belong to Bernal and Crowfoot's⁵⁴ ordered smectic category of liquid crystals. If the randomness is due only to the circumstance that thermal motion is insufficient to permit re-orientation of these planes into a regular

crystal pattern rather than being the thermodynamically stable condition, this structure should be regarded as an anisotropic glass.

The α form of the simple triglycerides²⁵ is probably also an example of the ordered smectic state, since the terminal groups lie in planes, and there is a fairly constant separation of the paraffin chains, which, however, are said to be frozen in

FIGURE 3. Relative Orientation of the Molecules in (a) the Rhombic Crystal, (b) Layer Structure of Paraffin Hydrocarbons. \bullet represents the projection of a hydrocarbon molecule on the $a-b$ crystal face. [After A. Muller, *Proc. Roy. Soc. London*, **A127**, 417 (1930).]

random orientation with respect to each other. The γ form of the triglycerides, obtained by quenching the liquid form, is, on the other hand, apparently more closely related to a nematic liquid crystal, since the terminal groups do not lie in planes (no long spacings appear), and the only regularity seems to be a parallel alignment of the chains. Because of its rigidity and also its metastability, this form has also been referred to as an anisotropic glass.

Mesomorphic Forms of the Sodium Soaps

As has been already pointed out, the sodium soaps* afford the most striking illustration of a stepwise melting process yet discovered. The x-ray studies necessary to complete understanding of the structure of each phase have not been carried out, although they have been begun in several laboratories.[†] The principal effort has thus far been directed toward finding the number and temperature ranges of existence of the phases for different soaps, and the relations between the phases of one soap and those of another. Recent calorimetric studies provide the experimental basis for initial speculations concerning the nature of some of the transitions.⁴⁴

Sodium palmitate has six definitely established transitions^{41, 42} in addition to the monotropic transition from the rhombic crystal to a monoclinic form⁴⁰ and the genotypic point.³⁸ At the high temperature extreme it is an ordinary isotropic liquid. At room temperature the substance normally exists as a monoclinic crystal. When sodium palmitate is prepared by evaporation of the solvent from an aqueous solution, its physical form is fibrous, individual fibers being exceedingly thin, sometimes as thin as two molecular lengths (electron microscope⁴⁵). This circumstance has resulted in frequent reference to the crystalline form of the soaps as "curd fibers" or "curd fiber phase." A rhombic crystal form can be prepared at room temperature by crystallization from ethyl alcohol.⁴⁰ It is possible^{44, p. 2020} that more than one monoclinic form can exist.

The naming of the known phases intermediate between crystalline sodium palmitate and liquid sodium palmitate reflects the history of their discovery and investigation. When one mesomorphic form was first recognized it was given the

* Recent unpublished experiments of the authors show that other alkali metal soaps also exhibit sequences of mesomorphic forms.

† F. G. Chesley, *J. Chem. Phys.*, **8**, 643 (1940). See also ref. 38, 39, 40. J. W. McBain, personal communication.

name "neat," because it was thought to be continuous in a phase rule sense with the anisotropic liquid of that name present in the commercial soap kettle.⁴⁶ Then a second intermediate form was discovered and called "waxy" because of its resemblance (in appearance) to paraffin. The names subwaxy, superwaxy, and subneat were assigned to subsequently discovered phases to indicate their position in the sequence. (subwaxy—waxy—superwaxy—subneat—neat.)

The neat soap phase of sodium palmitate is a translucent, viscous, doubly refracting fluid. Trapped bubbles are elongated because of the anisotropic character of the resistance offered by the liquid to expansion of the air. The phase separates from isotropic liquid either as globules (on which a uniaxial cross is visible through crossed Nicols with a polarizing microscope) or as batonnets. In very thin layers on glass neat soap becomes rapidly oriented, with the optic axis perpendicular to the glass so as to simulate isotropic behavior. Curiously, the orientation is more rapid near the center of the temperature range of stability of the phase than at higher temperatures.

FIGURE 4. Photomicrographs of sodium stearate by the hot-wire technique. Five of the six phases of sodium stearate appear successively as the temperature falls from about 350° near the wire (W) to about 140° at the right-hand edge of the photograph. A, boundary between isotropic liquid and neat soap; C, boundary between neat soap and subneat soap; D, boundary between subneat soap and superwaxy soap; E, boundary between superwaxy soap and waxy soap. The upper photograph was taken with the Micropolychromar, the lower, showing an adjacent portion of the same field of view, with crossed polaroids. Magnification is about 20 fold. At B the neat soap has begun to become oriented, simulating the appearance of isotropic liquid. [From Vold, M. J., Macomber, M., and Vold, R. D., *J. Am. Chem. Soc.*, **63**, 168 (1941).]

The subneat phase of sodium palmitate is also a translucent, plastic, optically anisotropic material. It is more rigid than neat soap. The size of uniformly oriented aggregates is smaller, and extensive orientation, as for neat soap on a glass surface, has not been observed.

Viewed in the microscope with white light through crossed polaroids, both neat soap and subneat soap appear as a mosaic of different colors which arise from the different thicknesses of uniformly oriented patches of liquid crystal. For neat soap

FIGURE 5. Typical Microscopic Appearance of Some of the Phases of Anhydrous Sodium Soaps. All photographs were taken with crossed Nicols at about 100-fold magnification. Photographs (a), (c), and (e) were taken by Michael Macomber.

uniformly colored areas are larger, and conic structures of the type described by Friedel,⁵⁸ Lawrence,⁵⁹ and others are frequently visible.

The complete series of phases can be viewed together when a thin film of material is subjected to a temperature gradient produced by a hot wire placed at the edge of the film.⁴² The films are too thin to exhibit polarization colors, but characteristic differences nevertheless appear, leading to sharply defined boundaries between the different phases. Figure 4 shows a part of the sequence for sodium stearate. Different methods of illuminating the sample were employed in order to render one or another boundary more conspicuous.

The "waxy" phases (subwaxy, waxy, and superwaxy) are very similar in appearance, at least in the case of sodium palmitate and sodium stearate. When prepared by heating or cooling a film of anhydrous material, they all display a granular stippled appearance without any obvious structural features or optical patterns. They differ most in translucency, superwaxy being the most nearly transparent, and subwaxy the least. This difference is largely responsible for the conspicuous boundaries seen in Figure 4. Figure 5 shows the characteristic microscopic appearance of several of these phases.

Even for the most thoroughly studied soaps, sodium palmitate and sodium stearate, the entire gamut of experimental behavior is not fully understood. Among the unsolved problems are the following.

First is the interrelation between the various crystal forms. Sodium stearate usually crystallizes from solvents in a rhombic form if the crystals form first below 50° C. This form undergoes an irreversible transition at 52° to a monoclinic form. However, the preparations always contained about 1% moisture, removal of which by room temperature dehydration destroys the capacity of the soap to exhibit any transition at 52°. Both in this dehydrated material, and in the slightly moist monoclinic form produced by the transition at 52°, the genotypic transition discovered by Thiessen and co-workers^{37, 38} is present, and appears to be reversible. However, this genotypic transition is absent from all preparations that have been heated hot enough to form subwaxy soap, and from some heated only hot enough to form "supercurd," even though both these transitions themselves seem reversible. Thus the number of crystal forms possible, and their relative stability are still undetermined.

Second is the relation between subneat soap and neat soap. This transition appears to occur (microscopic observations) at 253° C for sodium palmitate; a small but definite and reproducible reversible change in volume also occurs at this temperature. However, there is no observed change in heat content at 253°, while there is a reversible heat effect of 1540 cal/mole at 237° unaccompanied by visual or dilatometric evidence of a transition. Further, M. Heldman has found that an enormous increase in electrical conductivity occurs continuously in the entire range of temperature from 237° to 253°. Is this behavior subject to interpretation in terms of the structure of subneat soap, or must we admit the existence of yet another intermediate form?

Also there is the problem as to why orientation of neat soap on glass should proceed more rapidly at 270°, near the center of its temperature range of stability, than at the melting point (295° C), where it is actually in contact with mobile isotropic liquid.* (See Figure 4 for an illustration of this same effect for sodium stearate.)

* Since the above summary was written (December, 1941) further research, particularly on sodium stearate, has partially cleared some of the reported anomalies. Thus M. J. Buerger, L. B. Smith, A. De Bretteville and F. V. Ryer [*Proc. Nat. Acad. Sci.*, 28, 526 (1942)] find two of the reported crystal modifications of sodium stearate to be hydrates of very low water content. The transition of "sodium stearate" occurring at 53° appears to be the decomposition temperature of the hemi-hydrate. For discussion of recent x-ray work, see paper by R. S. Vold, *J. Am. Chem. Soc.*, 1943-4.

Similar sequences of mesomorphic forms have been investigated for the sodium salts of fatty acids from C_6 to C_{26} .^{42, 43, 44} This study provides more information about the individual transitions from the variation of transition temperature, heat of transition, volume increment of transition, etc., with the number of carbon atoms in the molecule. It appears that the sequence of phases is not always the same from soap to soap, so that the problem is more complex than originally supposed.

FIGURE 6. Transition Temperatures of Sodium Soaps. ○, visual and dilatometric values; □ calorimetric results significantly different from the former. Lines connect transitions presumed to involve similar changes in structure.

Figure 6 summarizes the results that have been obtained. Wherever there is any evidence that two transitions are of the same kind, *i.e.*, at least one of the two phases involved has the same structure for both soaps, the corresponding points have been connected by lines. The nature of the evidence is quite varied, similarities in appearance, volume increment, change in heat content, mutual solubility, and regular variation of temperature with number of carbon atoms all having been considered.

The transitions for sodium stearate are similar to those for sodium palmitate, except for the existence in the stearate of an additional change occurring prior to the formation of subwaxy soap. Though absent for sodium palmitate, this transition appears again for sodium myristate. It is absent for sodium laurate and apparently also for sodium arachidate. McBain has proposed to call this transition the formation of "supercurd phase."

Reference has already been made to the apparent occurrence of the neat-subneat

transition for C_{14} , C_{16} and C_{18} at a temperature lower according to calorimetric evidence than according to visual and dilatometric results. One or two other unexplained discrepancies of this character appear in Figure 6.

Aside from the additional transitions noted above, the sequence of phases appears to be similar for sodium myristate, palmitate and stearate, but not for sodium laurate. The formation of subwaxy soap from the crystal form stable at room temperature involves a change in heat content of the same order of magnitude for C_{14} , C_{16} , and C_{18} . For C_{12} the value is considerably smaller. This may reflect some difference between the crystal form of C_{12} and the others, since the transition from subwaxy soap to waxy soap is of the same character for all four. At the next transition, waxy-superwaxy, laurate behaves differently from C_{14} , C_{16} , and C_{18} in that there is for laurate a change in heat content of about 600 cal/mole. At the superwaxy-subneat transition all four behave similarly, while at the subneat-neat transition C_{12} again deviates, in this instance having no detected change in heat content as compared to a value of about 100 cal/mole extrapolated from the results for C_{14} , C_{16} , and C_{18} . That differences in behavior between C_{12} and the others should appear only at alternate transitions is at present quite inexplicable.

The curve of melting point as a function of the number of carbon atoms in the molecule is far from smooth. The break at C_{20} (sodium arachidate) can be ascribed to the fact that transformation to isotropic liquid takes place from subneat soap at and beyond C_{20} , but from neat soap below C_{20} . A further break between C_{12} and C_{14} has not been explained. It is, however, possibly to be attributed to differences in the nature of the liquid phase. For myristate, palmitate and stearate, the liquid is very viscous and contains microscopically visible patches of faintly anisotropic material, while for laurate the liquid is clear and mobile. The residual anisotropy diminishes with increasing temperature. In fact, Vorländer once reported 316° instead of 295° as the true melting point of sodium palmitate.⁴³

As the number of carbon atoms in the molecule increases, the temperature of final melting to isotropic liquid decreases, while that of the formation of a mesomorphic phase from the crystal increases; that is, the temperature interval in which mesomorphic forms exist is narrowed down. Presumably a soap of sufficiently high molecular weight would exhibit a single melting point, similar to the limiting value of about 117°C for other paraffin chain compounds.⁶¹ Consequently, as chain length increases, the temperatures of the several transitions are crowded together. At C_{20} the curve for the subneat-neat transition joins that for the melting points. Therefore, at C_{20} melting involves the same change in structure in a single step that takes place in two discrete steps for soaps of shorter chain length.

Transformation from crystal to liquid should require the same increase in heat content, regardless of the number of steps or separate transitions by which the process occurs. Values found for the sum of the heat effects of all the transitions are of the same order of magnitude as experimental results for the heats of fusion of the corresponding fatty acids (12,570 cal/mole for sodium palmitate, 13,030 cal/mole for palmitic acid⁶²).

Transitions which involve loosening of the hydrocarbon chains from one another can be expected to show considerable variation in heat effect with chain length. This is the case for the transition from crystal to subwaxy soap and from subwaxy soap to waxy soap. About two-thirds of the total heat of fusion is associated with these two transitions. Heats of transition for the remaining four changes are smaller, and vary but little with chain length (for the three substances sodium myristate, palmitate and stearate). Presumably the structural rearrangements are here largely concerned with the heads of the molecules.

Neat soap, the liquid crystalline form stable at temperatures just below the melting point, probably has a smectic structure. According to Hermann,³⁶ a liquid crystalline form of thallium palmitate (relation to the neat soap of sodium palmitate un-

known) has the terminal groups lying in definite planes, but randomly rather than regularly arranged. The conic structures (see for example Figure 5a) are further evidence of this structure.⁶³

Assignment of similarly detailed structures, even tentatively, to the remaining mesomorphic forms cannot be made without further experimental evidence. One direction of thought is that there are here a number of different kinds of constraints holding the crystal lattice together, and that these can be released one by one at different temperatures. At least six, and perhaps more, discontinuous steps must be thought of as occurring in the transformation from a crystal, containing pairs of oppositely oriented molecules disposed in a perfectly regular manner, to a liquid in which the molecules are, on the average, randomly arranged, with the hydrocarbon chains possibly not fully extended. Moreover, since the sequence of phases is not identical for all the soaps, alternative routes of stepwise lattice breakdown may have to be provided.

Another hypothesis* is that in some of the mesomorphic forms the fundamental unit is larger than the molecule; *i.e.*, two forms may have the same disposition of one molecule relative to its neighbors, and differ only in the character of the secondary structure, or the arrangement of such primary groupings of molecules. Whether or not *two discrete phases* can differ *only* in size or nature of such secondary aggregates can be answered only by further investigation.

In all the mesomorphic forms, microscopic or submicroscopic aggregates certainly do exist. This is evident from their appearance between crossed Nicols, the fact that they scatter light, etc. The existence of such aggregates might be thought of as similar to the mosaic structure of imperfect crystals.⁶⁴ The crystal form of the sodium soaps frequently has a fibrous structure in which individual fibers are very long and narrow (40-50 Å).⁴⁵ Whether or not there is a characteristic size of aggregate in any of the mesomorphic forms has not been determined.

Polymerization

H. MARK

Polytechnic Institute, Brooklyn, N. Y.

Definitions and General Survey

Polymerization processes are chemical reactions which combine small molecules by chemical valences to form very large ones. They occur with both organic and inorganic compounds, and usually result in solid materials of crystalline or vitreous character having outstanding thermal, mechanical, electrical, and optical properties. According to W. H. Carothers,² there are two main types of polymerization reactions: (a) A-polymerizations and (b) C-polymerizations.

The first group represents association polymerization which at present also is, for short, called polymerization. The reaction consists in a successive addition of molecules containing double or triple bonds, until a giant molecule is formed, in which the different parts are linked together by main valence bonds. Examples: Liquid sulfur polymerizes to long-chain molecules which represent elastic sulfur; ethane polymerizes to a long-chain substance called polythene.

The molecule which undergoes polymerization is called the *monomer*. The number of monomers linked together in one molecule is termed "degree of polymerization" or "polymerization degree" (*P*). If *P* is a number above 100, one speaks of high polymers; the lowest numbers of such a series of polymers are usually termed by the Greek prefix for their degree of polymerization, such as: dimer, trimer, tetramer, etc.

A series of molecules built up from the same monomer, but having different degrees of polymerization, belongs to one *poly-homologous series*. Many such series

are known; in some cases, polymerization degrees as high as 10,000 have been measured experimentally.

Such large molecules are called *macromolecules*, or *giant molecules*; if they have the form of a chain, they are also known as *main valence chains*. It has been observed that under certain conditions, two or more monomers are capable of entering the same macromolecule; this is called *copolymerization*, or *interpolymerization*.

Condensation (C) polymerizations take place if two or more bi- or multi-functional molecules combine, with the elimination of water. Such processes are also called *polycondensations*. Examples: NaOH and orthosilicic acid form polysodium silicate; glycol and adipic acid give polyglycol adipate.

The molecules (two or more) which enter the reaction are called *monomers*. The reaction products are again termed dimers, trimers, high polymers and eu-polymers according to their degree of polymerization. The resulting molecules again are macromolecules or giant molecules.

If only two-functional monomers participate, one gets only *chain polymers*, which are also called covalent chains. If one or more of the monomers are tri- (or higher) functional, two- or three-dimensional networks are obtained, and the degree of polymerization exceeds any measurable limit. In such a case, one observes *gelation*. Examples: hexamethylene diamine and adipic acid build up linear macromolecules belonging to one homologous series. Substances of this type are called *nylon*. Glycerin and phthalic acid build up macromolecules of a non-linear type having complicated three-dimensional structures with very high degrees of polymerization. Such substances are called *glyptals*.

Table 1 shows a few atomic groups which undergo A-polymerization with comparative ease and are therefore used to a large extent in the commercial production of synthetic elastomers and plastics. The first column contains the characteristic group of atoms which makes the material polymerizable; the second gives the name of one of the more important substances containing this group; and the third column lists a few trade names of products being built up by the systems under consideration.

Table 1.

| Atomic Groups | Name of Monomer | Trade Names of Polymers |
|--|-----------------|-------------------------|
| $\text{CH}_2 = \text{CH}_2$ | ethylene | Polythene |
| $\text{CH}_2 = \text{CHCl}$ | vinylchloride | Koroseal |
| $\text{CH}_2 = \text{CH} - \text{CH} = \text{CH}_2$ | butadiene | Buna |
| $\text{CH}_2 = \text{CCl} - \text{CH} = \text{CH}_2$ | chlorobutadiene | Neoprene |
| $\text{CH}_2 = \text{CHOOC} \cdot \text{CH}_3$ | vinylacetate | Vinylite |
| $\text{CH}_2 = \text{CH} (\text{C}_6\text{H}_5)$ | styrene | Victrone |
| $\text{CH}_2 = \text{CH} - \text{CO} \cdot \text{OCH}_3$ | acrylic ester | Lucite |

In Table 2 is the corresponding information about C-polymerizations. The first column shows pairs of two- or three-functional molecules, which are capable of condensing; the second column gives the names of a few products.

Table 2.

| Pair of Polyfunctional Monomers | Trade Names of Polymers |
|-------------------------------------|-------------------------|
| Glycerol = phthalic anhydride | Glyptal |
| Formaldehyde = phenol | Bakelite |
| Formaldehyde = urea | Pollopas |
| Adipic acid = hexamethylene diamine | Nylon |

Characterization of Polymers

One of the most important problems is the adequate characterization of macromolecules. Their empirical chemical formula is given by the formulas of the monomers and can, in most cases, be obtained by elementary analysis. Much more difficult is the determination of the size and shape of the macromolecules.

In practically all cases, there is no definite molecular weight, but the sample has to be described by a molecular size or molecular weight distribution curve, which gives the number of molecules having a polymerization degree between P and $P + dP$ as a function of P . It is called the number distribution curve of the molecular weight. More frequently, the weight distribution curve is employed; this gives the total weight of the material contained in molecules of a polymerization degree between P and $P + dP$ plotted against P . Fig. 1 shows such a weight distribution curve of a polystyrene sample prepared at 130°C . It can be seen that this material is rather heterogeneous, inasmuch as it contains a considerable amount of substance in the range as low as $P = 200 - 300$, and also a fraction as high as $P = 3000$. All natural and synthetic polymers are more or less non-uniform, and it seems to be an important question to what extent this heterogeneity affects their technical properties.

Sometimes one is satisfied to use *average values* instead of the whole distribution curve, and distinguish between the number average molecular weight, M_n , and the weight average molecular weight M_w . Both values can be directly derived from the corresponding distribution curves.^{4, 9, 11, 16}

The following experimental methods are used to determine these average values:

(a). The measurement of the osmotic pressure in very dilute solution (weight concentration c_w below 0.2 per cent) allows the computation of the number average molecular weight with the aid of the Van't Hoff equation:^{10, 14}

$$M_n = \frac{RT}{p} \cdot c \quad (1)$$

where

R = gas constant 7.2×10^7 erg/gram
 T = temperature ($^\circ\text{C}$)
 p = osmotic pressure in dynes per sq cm
 c = concentration in g per cc

The usual way to obtain p is direct measurement in an osmometer with a semi-permeable membrane.

(b). The determination of the number of end groups of a chain polymer by chemical means also permits the calculation of the number average molecular weight of the material. The end groups usually are either double bonds or aldehyde groups which give certain characteristic chemical reactions, and can thereby be determined analytically.^{1, 3, 5, 6, 7, 8, 17}

Aldehydic end-groups of, e.g., cellulose chains can be determined by their reducing power against Fehling's solution; double bonds as end-groups in polystyrene, by their ability to add bromine. Acidic or alkaline end-groups of poly-condensation products, such as nylon, can be titrated with monoacidic bases or monobasic acids.

(c). The specific viscosity of a very dilute solution of a high polymer (weight concentration below 0.1 per cent) allows the computation of the weight average molecular weight with the aid of the Staudinger equation:¹⁷

$$\eta_{sp} = K_m \cdot M_w \cdot c_m \quad (2)$$

η_{sp} = specific viscosity (relative viscosity increase due to the dissolved material).
 K_m = characteristic viscosity constant
 c_m = concentration in moles of the monomer per 1000 cc

Equation (2) is an empirical law, which holds with a certain approximation and is sometimes useful to figure out an approximate value for M_w . Staudinger has determined the K_m -constants for certain important high polymers in various solvents.¹

Instead of the specific viscosity, one can use to greater advantage the intrinsic viscosity, according to E. O. Kraemer.^{9, 10}

(d). The ultracentrifuge permits determination of the weight average molecular

weight by measuring the rate of sedimentation. Still another average value can be obtained by the sedimentation equilibrium method. Also, in these cases it is essential that the solutions investigated should be very dilute (weight concentration below 1.0 per cent).

Table 3 shows a series of values of weight average molecular weights for certain natural and synthetic high polymers. It can be seen that these values cover a fairly wide range and represent materials of considerable technical interest.

Table 3.

| Substance | Polymerization degree | Molecular Weight |
|------------------------|-----------------------|------------------|
| Rubber | 2000-4000 | 140,000-280,000 |
| Cellulose | 2000-3000 | 300,000-450,000 |
| Polyisobutylene | 1200-2400 | 60,000-130,000 |
| Polystyrene | 1000-2500 | 100,000-250,000 |
| Polyvinyl acetate | 400-1200 | 30,000- 90,000 |
| Polyglycerol phthalate | 100- 500 | 30,000-150,000 |

The distribution curves can be determined either in the ultracentrifuge, or by fractionate solution or precipitation of a given sample by the use of appropriate solvents and precipitants.

Another characterization is possible by distinguishing between polymers which are built up of chain molecules and those which present more complicated systems of cross-linked and cross-linked in two or three dimensions. It is not yet possible to give a completely clear distinction between chain- and net- or space-polymers; but generally it can be said that chain polymers are usually soluble in appropriate liquids, while the latter substances merely swell. A certain amount of the material goes into solution, but the main mass simply absorbs the swelling agent without losing its own coherence.

Such three-dimensional polymers have exceedingly high molecular weights, and with a certain degree of justification the whole sample may be considered one single giant molecule. As they are insoluble, it is as yet impossible to carry out any of the above-mentioned methods for determination of the degree of polymerization, and a suitable method for their characterization has not yet been developed.

The Formation of Macromolecules

The mechanism of the formation of macromolecules has not yet been elucidated in all its details, but it is possible to give at least a general description of the most important elementary steps.

In the case of C-polymerizations, the situation seems to be comparatively simple. According to Carothers² and Flory,⁴ these reactions consist of a very large number of elementary steps of esterification, anhydridization, etherification or amidification. All consecutive steps are identical with the foregoing, and the whole chain or space-polymer is held together by covalent chemical bonds of identical character.

It seems that A-polymers are produced by a considerably more complicated mechanism. Its essential elementary steps seem to be (a) the activation or start reaction; (b) the propagation or growth reaction; (c) the termination or break reaction.

In certain cases, still other steps, such as branching, ring closure, chain transfer, and so on, may occur and interfere with the steps mentioned above.

Activation processes. It seems that the first step of a polymerization reaction is the activation of certain molecules of the monomer. This activation can be effected by the absorption of a light quantum by simple thermal collision or by the aid of a catalyst. Table 4 shows the activation energies for the starting reaction for a series of polymerization processes. It can be seen that the order of magnitude corresponds to that of a chemical process during which covalent bonds are opened and closed.

We may therefore formulate the activation step as the formation of a radical or biradical, according to the equations:

Table 4.

| Reaction | Activation Energy |
|-----------------------------|-------------------|
| Polymerization of acetylene | 40,500 |
| ethylene | 35,000 |
| styrene | 26,000 |
| vinylacetate | 25,000 |
| indene | 26,000 |
| butadiene | 24,700 |

In some cases, however, it seems to be more appropriate to consider the activated state as being the double bond in one of its excited electronic states, without actually having the double bond opened:

In the first case, the starting reaction is very slow as compared with all other elementary steps, and each nucleus will grow very quickly in a long-chain molecule as soon as it has been formed. The average lifetime of the activated centers (growing chains) is presumably below $\frac{1}{100}$ of a second. This free-radical mechanism seems to work during the heat polymerization of styrene, vinylchloride, vinylacetate, acrylic esters, etc.

The activated double bond mechanism, on the other hand, has been observed with the photochemical polymerization of methacrylate and the sodium-catalyzed polymerization of butadiene.

The formation of nuclei with successive growth of these nuclei is a process which shows a close analogy to the phenomenon of crystallization. G. Tammann in his book "Crystallization and Fusion" has developed the idea that the presence of certain centers or nuclei is essential for crystallization and that the slow formation of those nuclei is responsible for the phenomenon of supercooling.

The propagation reaction. If a monomeric molecule collides with an activated center, a process of growth takes place according to the equation:

In the case of the radical chain mechanism the activation energy of propagation^{11, 16} is very low (around 4000 or 5000 cal per mol monomer), and this accounts for the fast propagation and the short average lifetime of the chains.

In the case of the activated double bond mechanism, the activation energy for the propagation seems to be somewhat higher (6000-10000 cal per mol of the monomer) which would account for the higher stability of the intermediate products.^{11, 18}

The experimental measurement of those activation energies is accomplished by creating a certain number of active molecules in the monomer and then determining the rate of polymerization at different temperatures.

It seems that one and the same monomeric substance can undergo both types of polymerization according to the experimental conditions, and that even under given conditions both types of growth can take place simultaneously.

The termination reaction. Experience shows that chains do not grow indefinitely but are terminated by some additional chemical process. Radical chains are very sensitive, and can be broken in many different ways:

(1) A collision of two free radical chain ends leads to a mutual saturation and to the disappearance of two active centers. This process can be expressed by the formula:

(2) A collision of a free radical chain end with an unactivated monomer usually leads to a step of propagation, but sometimes a so-called chain transfer takes place according to the equation:

(3) The two free ends of the chain can saturate each other by the formation of a poly-membered ring.

(4) Many substances—deliberately added or present as impurities—react with the free valencies at the chain ends and therefore stop the further growth of the molecule. They are usually called inhibitors or stabilizers.

(5) The migration of a hydrogen atom from one end of the chain to the other also leads to a removal of both free valencies according to the equation:

and hence to a termination of growth of the molecule under consideration.

It has been possible^{1, 4, 10, 11, 12, 13, 15, 16} to work out general formulas for the interference of the different elementary steps listed above, and it can be said that in several cases, a satisfactory agreement with the observed data has been obtained. It seems, therefore, that the above scheme covers the majority of the observed polymerization reactions and provides a possibility of dividing them into their different elementary steps.

Fundamental Aspects of the Elasticity of Rubber and of Rubberlike Materials

EUGENE GUTH

Department of Physics, University of Notre Dame, Notre Dame, Indiana

Introduction

Rubber is one of the most important colloidal materials. In addition to its widespread use in daily life, it may be considered as a simple prototype of important biological substances, like the proteins. Rubber is much more unstable than a metal or a glass. This very instability permits an amazing versatility of change in its structure and properties. It can be made electrically conducting or brought into a glassy state. It belongs to a class of substances which nature uses as a framework for all living things. Its study, though developed by the necessities of daily life, is deeply interconnected with all those sciences which make a fundamental inquiry into organic life: biochemistry; biophysics; physiology and pathology, dealing with nerve and muscle; vitamins and proteins.

Rubber chemistry and technology may be considered as an important link in the monumental attempt of human mind to unveil the mystery of organic life. The development of rubber technology starts with the discovery of the latex of *Hevea brasiliensis*, for in this tree nature is a manufacturer of rubber. After discovering the latex and its transformation into solid crude rubber by the typical colloidal process of coagulation, the next important step was the discovery of vulcanization by Goodyear in 1839. Though unknown to Goodyear, vulcanization is also an imitation of an artifice of nature to preserve an organic material from decay and make it more enduring. Wool protein, or keratin, contains sulfur as a protective agent. Hair consists of such "vulcanized" protein, and may last a long, long time after the "crude" (*i.e.* unprotected) proteins of an animal body have disintegrated. The synthesis of rubberlike materials, though (like vulcanization) developed mainly through needs of daily life, is a successful attempt of mankind to replace nature as a manufacturer of rubber or to find substitutes for this substance.

The aim of this paper is to present a simple picture of the interrelations of the elasticity and structure of rubber and of rubberlike materials. The theoretical work by H. M. James and the author¹ and the experimental work by the author's associates² at Notre Dame University will principally be considered. Unfortunately, there is neither time nor space to permit a critical appraisal of the excellent work of other investigators.

A series of interesting articles appeared on rubber in Vol. III and Vol. IV of this series* which may very well form a background to the present article. The most complete book on all aspects of rubber is "Chemistry and Technology of Rubber" edited by C. C. Davis and J. T. Blake.[†]

The most characteristic properties of rubber are, undoubtedly, its long-range reversible elasticity and its anomalous thermoelastic behavior. These properties are so characteristic that all materials having them may be called "rubber," or elastomers regardless of their chemical composition. When, in the following, we speak of rubber, we mean both natural and synthetic rubber possessing the aforementioned characteristic properties to a marked extent. Most practical uses of rubber are connected with its high reversible elasticity.

A substance possessing such an unusual elasticity must obviously differ greatly in structure from other materials, and conclusions regarding its structure may be drawn from its observed elasticity. To anticipate one of our main points: the elas-

* The articles by P. P. von Weimarn in Vol. III, and by E. B. Spear, Vol. IV; also in the same volume the articles by A. van Rossem, R. P. Dinsmore and N. A. Shepard.

† Reinhold Pub. Corp., N. Y., 1937.

ticity of rubber may be explained quantitatively on the basis of a very general model. Without a detailed knowledge (such as we do not now possess) of the structure of unstretched rubber, comparison of theory and experiment permits conclusions about some details of the model.

Fundamental Experiments on Elasticity

The manifold uses of rubber in daily life are based mainly on its remarkable physical properties. In order to obtain compounds with desirable properties for specific applications, compounds of varying composition are made, and then a series of physical tests is applied to find out the compositions needed for a particular application. The compounding and curing, *i.e.*, the chemical part of this process though important, is more incidental. Compounds of widely different composition may give the same essential physical properties. The physical tests applied may be characterized here merely by their name as, for instance, rebound, plastometer, flexometer, stress-strain curve, tensile strength, and so on. However, in these physical tests rubber undergoes a rather complicated deformation. This makes it difficult to correlate directly the results of the usual physical tests with the structure of rubber. Moreover, some of these tests may be closely related so that the results of the one test can be predicted from those of another.* From the practical point of view it is desirable to reduce the number of tests to a minimum, using only those giving independent results. From the theoretical point of view it is desirable to design a set of simple, fundamental experiments on elasticity of rubber and the results of such experiments should show a simple correlation to the structure of rubber. In turn these fundamental experiments may indicate an evaluation of the physical tests in terms of rubber structure. So we have the sequence: rubber structure \rightarrow fundamental experiments \rightarrow physical tests.

Fundamentally, rubber shows three thermoelastic effects; (1) it generates heat on fast stretching; (2) if stretched by a constant load (isotonic stretch) it contracts visibly when heated; (3) the stress in rubber kept at constant extension (isometric stretch) increases with rising temperature. Another fundamental fact is the S-shape of the stress-strain curve of rubber and its continuation for compression.

Unaware of earlier observations of Gough (1805) and Page (1847), Joule (about 1855) discovered independently the first thermoelastic effect of rubber, namely that it generates heat on fast stretching. William Thomson (Lord Kelvin) then pointed out to Joule that, according to thermodynamics, the second thermoelastic effect must occur, namely that rubber stretched by a constant load will contract on heating. As a matter of fact, this prediction of Lord Kelvin constituted one of the earliest applications of the second law of thermodynamics and Joule promptly verified the prediction experimentally.

Fig. 1 shows the change in temperature which Joule observed on fast stretching of a strip of vulcanized rubber.³ It is seen that a small cooling was observed for the lower elongations. However, at a critical extension, defining a thermoelastic inversion point, the change in temperature becomes zero. At extensions above this critical extension there is a rise in temperature. Normal solids, like metals, glasses and wood, show a cooling effect on fast stretching. The elastic behavior of rubber is normal only at small extensions, but it is anomalous above the thermoelastic inversion point.

Fig. 2 shows the contraction which Joule observed on heating a sample of vulcanized rubber. Again a thermoelastic inversion point appears.

The third thermoelastic effect, namely the rise of stress in isometrically (*i.e.*, at

*To mention an example from the related field of metals: Hardness measurements constitute one of the simplest non-destructive types of tests for metals. Now, for steel there is a correlation between hardness and tensile strength. Thus in many cases it will not be necessary to carry out the (destructive) tensile strength test; its result may be predicted from the measured hardness.

FIGURE 1. Change of temperature ΔT on fast stretching as a function of the strain ϵ according to Joule.

FIGURE 2. Linear thermal expansion coefficient $\alpha_{||}$ parallel to the direction of the stress as a function of the strain ϵ according to Joule.

constant length) stretched rubber with increasing temperature, was not investigated until recently.

Figs. 3a and 3b show isometrics obtained by the author's associates at Notre Dame. Again the existence of a thermoelastic inversion point is clearly evident.

The first stress-strain curves on rubber were taken by Villari. Fig. 4 shows a stress-strain curve obtained by Villari for rubber cord. This curve exhibits nicely the characteristic S-shape of the rubber stress-strain curves. The dashed compression branch is taken from data of Sheppard and Clapson.⁴ The rubber compound they investigated differed of course from that used by Villari.

FIGURE 3a. Stress-temperature curves (isometrics) at various extensions for an unaccelerated pure gum stock.

Any theory of rubber elasticity must explain the three thermoelastic effects and the S-shape of the stress-strain and compression curve quantitatively. Such a theory was developed by H. M. James and the author¹ and will be described briefly in the later sections of this article. The next sections contain a short discussion of the molecular structure of rubber.

Structure of Rubber

The Rubber Molecule. There are five main questions connected with the structure of rubber. The first concerns its elementary formula. This may be deduced from purely chemical facts and turns out to be $(C_5H_8)_n$. The second question pertains to the structure within the (C_5H_8) groups. Chemistry shows that this structure is:

containing one double bond and three single bonds (isoprene). The third question concerns the relation of the isoprene units to one another, *i.e.*, whether rubber is in the *cis*- or the *trans*-configuration; the fourth question relates to the degree of polymerization n . Physicochemical data, especially x-ray analysis, show that rubber is in the *cis*-configuration and that n is very large. The rubber "molecule" consists of a long chain of isoprene units:

FIGURE 3b. Same as 3a for larger extensions.

These four questions are the only ones which arise in more or less dilute solutions of rubber.

Since rubber is a solid there must be more or less perfect connections, or linkages, between the hydrocarbon chains; otherwise rubber would behave as a liquid and would flow if deformed. The fifth question we now raise pertains to the structure of bulk rubber.*

FIGURE 4. Stress-strain curve for a rubber cord according to Villari. The dashed curve represents compression data by Sheppard and Clapson.

For solid bulk rubber the concept of a rubber "molecule" will not in general be applicable. The situation is similar to that in the case of diamond, for instance. One may consider a whole macroscopic piece of diamond as a single giant molecule, but there is little physical sense in considering "molecules" of diamond, since diamond forms a regular network, or lattice.

The Theory of Gelation. Until recently the term "gel" was only vaguely defined and any theories of gelation were necessarily qualitative in nature. Recently, however, definite progress leading to a statistical treatment of "gelation" was made mostly by Flory,⁷ and followed by Stockmayer.⁷ We shall follow closely in this section Flory's excellent review. The term "gel" will be applied to insoluble, infusible three-dimensional polymers. A polymerization process leads to gelation, if an intermolecular reaction incorporates tri- or higher functional molecules. These molecules join together at random, to form network aggregates. Flory derived the critical conditions for the formation of infinite networks, finite clusters of molecules and for the coexistence of finite clusters with infinite networks.

* Spear, *l.c.*, mentions that the relation of the rubber molecules to one another in bulk rubber "has not received all the attention it deserves."

Flory also treats the more difficult problem of the composition of three-dimensional polymers. He obtained solutions for two cases: (a) bi- and tri-functional units joined at random and (b) chains of uniform length cross-linked at random at various points.

The weight fraction of molecules composed of a finite number of chains is given by the Poisson distribution:

$$W_n = \frac{n^{n-1}}{(n!)^2} (\gamma e^{-\gamma})^n \quad (1)$$

where γ , the "cross-linking index" is defined as the number of cross-linked units in the entire polymeric mixture divided by the total number of chains. The degree of cross-linking, *i.e.*, average number of cross-links per chain, is given by $\gamma/2$, two cross-linked units being involved in each cross-linkage.

When $\gamma \leq 1$, the summation ΣW_n over the weight fractions of all finite species is less than unity and equal to $W_s = \gamma'/\gamma$ where $\gamma' e^{-\gamma'} = \gamma e^{-\gamma}$ defines γ' , W_s represents the weight fraction of the sol (finite clusters of chains), and γ' measures the cross-linking index of this sol fraction.

$$W_g = 1 - \gamma'/\gamma \quad (2)$$

represents then the weight fraction of the gel (infinite network). The cross-linking index γ'' for the gel fraction is given by $\gamma'' = \gamma + \gamma'$. $\gamma = 1$ represents the critical point for incipient formation of infinite gelation networks. There $\gamma' = \gamma = 1$ and $\gamma'' = 2$. [For limitations of (2) cf. Stockmayer⁷ *l. c.* pp. 49-50]

The treatment of non-uniform chains is more complicated and has not yet been carried out. It can be seen, however, that non-uniformity of the chains will reduce the critical value of γ . [cf. however Stockmayer⁷]

Flory points out that gelation-network polymers should be characterized not by an average molecular weight (since a portion of the material possesses essentially infinite molecular weight). Rather he recommends two fundamental quantities: (a) the number of branch units or of cross-linkages per chain, (b) the number average chain length or chain molecular weight. Determination of the weight fraction of the gel will give (a), using formula (1). Therefore formula (2) then yields γ' , the degree of cross-linking in the sol fraction. γ' combined with the so-called number average molecular weight \bar{M}_n^* (= weight of the sample divided by the total number of molecules) determines the average chain length.

Flory discusses applications of his theory of gelation to rubber. Kemp and Peters have shown that the sol fraction of rubber films carefully prepared from latex is ten per cent or less, *i.e.*, $W_s = 0.1$ and $W_g = 0.9$. The presence of a gel fraction in raw rubber is probably due to occasional cross-linkages between the polyisoprene chains. According to Flory's theory, the division of rubber into two separate fractions of (practically) the same chemical composition is a natural consequence of the random cross-linkage of the long rubber chains.

Assuming, for orientation, the polyisoprene chains to be of uniform length, $W_g = 0.9$ leads to $\gamma = 2.5$ for the latex rubber films of Kemp and Peters; thus there are 1.25 cross-linkages per chain.

From $\bar{M}_n = 300,000$ (obtained from osmotic pressure measurements) a number average chain molecular weight of about 200,000 follows, assuming about one cross-linkage per two or three chains. Possible degradation and the non-uniformity of the chains would tend to increase this value, perhaps up to 1,000,000, *i.e.*, to a degree

* \bar{M}_n may be obtained by end-group determinations or measurements of the colligative properties of polymer solutions.

of polymerization of about 10,000 isoprene units per chain. This estimate leads to the very low value of about one cross-linkage per 8000 structural units.

Free Rotation in the Rubber Chains. In an isoprene group three out of the four C-C bonds are single and only one is double. Both quantum mechanics and experiment show that there can be free rotation around a single C-C bond. On the other hand, theory and experiment agree that a double bond is rigid and defines a certain plane which is characteristic of the group containing a double bond.

Free rotation, as used here, means only that there are different configurations (stable arrangements) of equal relative probability. The configurations might be separated by energy barriers, so that a free rotation in the literal sense does not take place. Nevertheless, if the barriers are not too high, a relative equilibrium of the different relative configurations may occur in a short time.

Measurement of the heat capacity of ethane indicates that the energy barrier hindering the free rotation of the two CH_3 groups relative to each other is of the order of 3kcal/mole. However, for isoprene the presence of the double bond may very well lower the barrier by a factor of 3 or more. In fact, for dimethylacetylene ($\text{CH}_3 - \text{C} \equiv \text{C} - \text{CH}_3$) the presence of the triple bond lowers the barrier so much that the two CH_3 groups rotate almost freely relative to each other. These points seem to have been overlooked by Bresler and Frenkel, in their attempt to calculate the influence of the potential barrier on the contracting force in single long hydrocarbon chains.*

Structure of Bulk Rubber. In the section on gelation it was shown that raw rubber consists of long chains interlinked by a few cross-bonds to a three dimensional gelation network. In this infinite network as a matrix there may be embedded finite clusters of chains, only loosely connected with the network, corresponding to a sol component in the gel matrix.

The Bundle Model and Its Statistical Treatment

In the first semi-quantitative treatment of rubber elasticity by Guth⁹ and co-workers in 1934 a simplified model was used for bulk rubber: a bundle of parallel chains or strings running through the whole piece of rubber, let us say a unit cube with its axes parallel to three coordinate axes x, y, z . If M designates the number of chains per unit cross-section, then a unilateral stress, Z , acting on two sides of the cube, say in the Z -direction, will be carried equally by the M strings. Therefore, it is sufficient to consider the behavior of one chain under the action of a stress Z/M and derive an equation of state for this chain.

This problem is closely related to the derivation of an equation of state for a gas and may be solved in an entirely similar fashion.

A string of rubber molecules may be considered as analogous to a gas whose molecules are tied together by flexible strings. The string must be flexible because of the free rotation. If there were no strings the heat motion would cause an expansion of the gas. The presence of the string will cause a coiling up of the resulting chain in a random fashion. To mention a simple illustration: an actual piece of flexible string thrown into the air will come down in a coiled, rather than in a straight form because of the greater probability of coiled configurations in contrast to the less probable straight configuration.

The quantitative treatment of our rubber chain is again very similar to the case of a gas. For simplicity we may consider an ideal gas. A configuration of gas molecules is the more probable the greater the volume the gas molecules occupy. Therefore, it is plausible to put this configurational (or thermodynamic) probability, C , proportional to the volume, V :

$$C(V) = A \cdot V; A = \text{constant} \quad (3)$$

* Recently a detailed criticism of the treatment of Bresler and Frenkel was given by Flory and Rehner⁸.

In order to derive an equation of state we have to connect the configurational probability $C(V)$ with the entropy $S(V, T)$ of the gas. Obviously, nature will prefer more probable configurations to less probable ones. This tendency of nature means that the entropy will change in conformity with the configurational probability: a statement qualitatively equivalent to the second law of thermodynamics. Quantitatively, the connection between $S(V, T)$ and $C(V)$ is given per molecule by Boltzmann's principle:

$$s(V, T) = k \log C(V) = k \log (A \cdot V), \quad (4)$$

and per mole with N molecules introducing the gas constant $R = Nk$

$$S = Ns = R \log (A \cdot V) \quad (5)$$

The equation of state $p = p(V, T)$ follows from the entropy by purely thermodynamic considerations:

$$p = T \left(\frac{\partial s}{\partial V} \right)_T = \frac{RT}{V} \quad (6)$$

For a rubber chain containing N freely rotatable links, the configurational probability $C(L)dL$ will be a measure of the probability that the ends of the chain will be apart by a distance between L and $L + dL$. It is natural to expect that $C(L)$ will have the form of the error law, *i.e.*, of the Gaussian distribution:

$$\left. \begin{aligned} C(L)dL &= B e^{-\beta L^2} dL; B = \text{constant} \\ \beta &= \frac{3}{2} \frac{1}{Nl^2}; l_r = l \tan \frac{\delta}{2} \end{aligned} \right\} \quad (7)$$

with l equal to 1.54\AA , the distance of the C — C bond and δ equal to 109° , the valence angle. Rigorous analysis, which we omit here, verifies this expectation.

Equation (7) corresponds to equation (3). To the volume, V , of a gas there corresponds the length L between the ends of the rubber chain.

Again Boltzmann's principle will connect the configurational probability $C(L)$ with the entropy $s(L, T)$ of the rubber chain:

$$s(L, T) = k \log C(L) = k \log B - k\beta L^2 \quad (8)$$

and for a *bundle* of M parallel chains

$$s(L, T) = M \cdot s(L, T) \quad (9)$$

This equation of state $Z = Z(L, T)$ where Z designates the force (normalized to unit original cross-section) stretching the rubber follows from the entropy by the analogue of equation (6):

$$Z = -T \left(\frac{\partial S}{\partial L} \right)_T = M \cdot 2\beta \cdot kT \cdot L = KTL \quad (10)$$

Applied to bulk rubber L may be interpreted as relative length, *i.e.*, extended length/original length.

This equation does explain *qualitatively* the three thermoelastic effects exhibited by rubber and holds *quantitatively* fairly well for medium extensions.

Thermoelastic Effects. 1. For the rise in temperature ΔT on fast stretching thermodynamics yields the formula:

$$\Delta T = \frac{T}{C_L} \int_1^L \left(\frac{\partial Z}{\partial T} \right)_L dL \quad (11)$$

Inserting the value of $(\partial Z / \partial T)_L$ using (10) one obtains:

$$\Delta T = \frac{T}{C_L} \cdot \frac{K}{2} \cdot (L^2 - 1) \quad (12)$$

This formula explains the experimental results given in Fig. 1, above the thermoelastic inversion point but it fails both for lower and higher extension.

2. The isotonic stretch may be characterized by the linear thermal expansion coefficient parallel to the direction of the stress,

$$\alpha_{\parallel} = \frac{1}{L} \left(\frac{\partial L}{\partial T} \right)_Z \quad (13)$$

α_{\parallel} may be computed from (10) using the thermodynamic relation:

$$\left(\frac{\partial L}{\partial T} \right)_Z = - \left(\frac{\partial L}{\partial Z} \right)_T \left(\frac{\partial Z}{\partial T} \right)_L ; \quad (14)$$

one obtains:

$$\alpha_{\parallel} = -\frac{1}{T} \quad (15)$$

i.e., the linear thermal expansion coefficient of stretched rubber has exactly the same magnitude (in the approximation of equation (10)) as the cubic expansion coefficient of an ideal gas but with a negative sign. Thus, equation (15) explains why rubber stretched isotonically contracts visibly when heated; α_{\parallel} (in the approximation of equation (10) is quite unrelated to the linear expansion coefficient of *unstretched* rubber, which is of the order: $2 \cdot 10^{-4}$. Again equation (15) only holds well above the thermoelastic inversion point.

3. For isometric stretch, equation (10) shows the (proportional) increase of stress with temperature.

Larger Extensions. The upward curvature of the stress-strain curve as shown in Fig. 4, may be explained on the basis of the bundle model. For it can be proved that the Gaussian distribution (7) holds only if the "length" L between the ends of the chain is small compared to the maximum length, which the chain has if it is completely straightened out by stress. For a simple one-dimensional model described in the Appendix of this paper, the maximum length is

$$L_{\max} = l \cdot N \quad (16)$$

where N is the number of links. The condition for the validity of the Gaussian distribution reads:

$$L \ll L_{\max} \text{ or } t \ll 1; t = L/L_{\max} = L/Nl \quad (17)$$

The generalized distribution derived in the Appendix is

$$C(L, N) = \frac{2}{(2\pi N)^{1/2}} \exp \left(-\frac{N}{2} \int \log \frac{1+t}{1-t} dt \right) \quad (18)$$

since

$$\log \frac{1+t}{1-t} = 2 \left(t + \frac{t^3}{3} + \dots \right) \quad (19)$$

(18) reduces to the Gaussian distribution if only the first term in the parenthesis is retained. Inserting $C(L, N)$ from (18) into equations (8), (9) and (10) we obtain:

$$Z = M \cdot \frac{kT}{l} \cdot \frac{1}{2} \log \frac{1+t}{1-t} \quad (20)$$

Introducing the quantity

$$f = \frac{Zl}{kT} \cdot \frac{1}{M} \quad (21)$$

we can transform (20) into the form

$$\dot{Z} = M \cdot \frac{kT}{f(t)} \cdot \text{with } f(t) = \tanh^{-1}t = \frac{1}{2} \log \frac{1+t}{1-t} \quad (22)$$

FIGURE 5. Inverse Langevin function (I) and inverse tanh function (II).

The function $t = \tanh f$ occurs in Ehrenfest's theory of magnetism. The function $f(t)$ is shown as curve II in Fig. 5. This curve explains the upward curvature of the rubber stress-strain curves simply as due to deviations from the Gaussian law as the chains are straightened out more and more by the stress.

A three-dimensional model corresponding to the one-dimensional model just treated, yields

$$f(t) = \mathcal{L}^{-1}(t); \quad -\mathcal{L}(f) = \coth f - \frac{1}{f} \quad (23)$$

where $\mathcal{L}(f)$ is the Langevin function known from Langevin's theory of paramagnetism and Debye's theory of polar molecules. The physical reason for the appearance of the Langevin function and of the function $t = \tanh f$ in the theory of rubber elasticity is elaborated in the Appendix of this paper.

The inverse Langevin function is shown as curve I in Fig. 5. The curve $3 \tanh^{-1} t$ deviates from $\mathcal{L}^{-1}(t)$ only when t approaches 1.

Thus the bundle model does explain the anomalous thermoelastic properties of rubber. It also explains the shape of the stress-strain curve at medium and larger extensions.

Limitations of the Bundle Model. The bundle model has, however, the following shortcomings. (a) It is an essentially one-dimensional model, stretchable only in the direction of the axis of the bundle. $\alpha_{\perp}(L)$, the linear thermal-expansion coefficient perpendicular to the direction of the stress cannot be computed. (b) It does not hold for small extensions and for compression. (Hooke's law holds in the limiting case of very small extensions). It gives $Z > 0$ for $L = 1$, and $L = 0$ for $Z = 0$

i.e., a volume zero for the unstretched state. (c) It does not explain the thermoelastic inversion point.

The New Model: Irregular Network and Internal Pressure

We know from the theory of gelation that even in raw rubber we do not have a bundle of isolated long-chain molecules. Rather, the long-chain molecules form a coherent mass by some sort of cross-linking. There must exist strong forces between the molecules to prevent their slipping past one another. Otherwise raw rubber could not be elastic, but would show as much plasticity as beeswax and chewing gum, which substances; when stretched, do not retract to any extent.

In the vulcanization process the cross-links already present in raw rubber are reinforced and new ones formed. Cross-links may be primary and secondary bonds. This general picture of the network structure of rubber is sufficient for the theory developed here.

For soft rubber, even after vulcanization, there are only a few cross-links per chain. Although a translation of the chains with respect to one another is suppressed, there is enough freedom of motion of the chains to make possible a free rotation around single bonds in the sense explained before.

We take as our model a region crossed by a complicated network of chains, very irregular in detail, but homogenous on the average. The chains may run between perpendicular plane boundaries of the volume of the rubber over which their ends will be uniformly distributed. The flexible chain molecules are bonded into the network by steric forces.

One action of the network will be a pull, the development of a contracting force due to the tendency of the chains of the network to coil up because of free rotation. This contracting force would lead to a collapse of the network if there were not present another action of the network exactly balancing the contracting force.

The second action of the network is due to the effects of molecular bombardments on the bounding surfaces. The chains jerk at the boundaries of the bulk material. In addition there may be inert clusters of chains (a sol component) present but not connected with the network. Both molecular bombardments on the bounding surfaces and sol component will lead to the production of a pressure as in an ordinary liquid.

In our model we separate rather sharply the two actions of the network: the contracting pull of the network due to the tendency of the chains to coil up, and the hydrostatic pressure, due to the sidewise pushes of the chains. We compute the first action, the pull of such a network directly, but represent its second action, the production of internal pressure, simply by filling the model with a fictitious * liquid, the "rubber liquid," which in a good approximation one may take as incompressible. Any surface of the model must, of course, be in equilibrium under all the forces which act on it—the pull of the network, the push of the hydrostatic pressure, and any external forces.

Equation of State for Incompressible Rubber Consisting of Gaussian Chains

Let us consider the irregular cross-bonded network as described above. It can be proved² that this network can be replaced by a regular network of cubic symmetry. The independent chains of this regular network may run parallel to the three coordinate axes. For this network it is easy to obtain the equation of state for stretched rubber.

We make two fundamental assumptions:

I. The Gaussian distribution is valid for $C(L)$, the configurational probability; *i.e.*, the rubber chains are extended only to a length small compared to their maximum length;

* This "liquid" is fictitious as far as it simulates effects of steric forces and molecular bombardments but is more real as far as it represents a largely non-extractable sol component *i.e.* branching.

II. Rubber is incompressible, *i.e.*, it does not change its volume when stretched.

Assumption II holds experimentally for soft gum compounds up to about 300 per cent extension, according to Holt and McPherson.¹⁰

Let us consider a unit cube of unstretched rubber. After a force Z is applied in the z -direction, the dimensions of the resulting parallelepiped will be L_x, L_y, L_z . For unilateral deformations we have the relation

$$L_x = L_y \quad (24)$$

According to our assumption II and (24)

$$1 = V = L_x L_y L_z = L_y^2 L_z \quad (25)$$

As described earlier, there will be three forces acting in our model:

Z_1 , the inward pull due to the contracting force;

Z_2 , the outward push due to the internal pressure of the rubber liquid; and

Z_3 , the outward pull due to the external force.

Because of the equivalence of the irregular and of the regular cubic network, we may use for the contracting force the expression (10) derived for an isolated chain. Then

$$Z_1 = KT \cdot L_z \quad (26)$$

The internal pressure P may be calculated from the condition of the equilibrium of the forces applied to one of the sides (L_y, L_z) of the cube on which no external force acts. The outward push of this pressure is balanced by the pull of M molecular chains, each extended to length L_x and thus exerting an average force of $Z_x = KT \cdot L_x$. Then,

$$PL_y L_z = KT \cdot L_x; \quad (27)$$

using (24) we obtain

$$P = KT \cdot 1/L_z \quad (28)$$

Thus the internal pressure of rubber decreases for tension and increases for compression in accordance with physical expectations.

Considering the forces acting on the end (L_x, L_y) faces, we have

$$\begin{aligned} Z_1 &= KT \cdot L_z \\ Z_2 &= PL_x L_y = KT \cdot 1/L_z^2 \end{aligned} \quad (29)$$

For equilibrium between these three forces, the sum of the outward forces must be equal to the inward pull, or

$$Z_2 + Z_3 = Z_1 \quad (30)$$

Inserting the value of Z_1 and Z_2 , we obtain

$$Z = Z_3 = Z_1 - Z_2 = KT[L_z - 1/L_z^2]. \quad (31)$$

This is the stress-strain relation we were looking for. Physically, it states that the external force balances the difference between the tension due to the internal Brownian motion and that due to the internal pressure.

The stress-strain relation (31) holds both for extension ($L_z < 1$) and for compression ($L_z > 1$), thus removing an outstanding difficulty of the bundle model. It holds also, of course, for small extensions. At large L (31) has an asymptote intersecting the Z -axis at $L = 0$; at small L (31) has the Z -axis as its asymptote.

Fig. 6 curve B is an observed stress-strain curve obtained at Notre Dame. The circles are theoretical values according to equation (31). The knee of the observed curve is explained well by the theory.

Young's modulus, E , may be defined as the slope of the stress-strain curve given by equation (31):

$$E(L_s) = \frac{dZ}{dL} = KT \cdot \left[1 + \frac{2}{L_s^2} \right] \quad (32)$$

E has for $L_s = 1$ the value

$$E(1) = 3KT, \quad (33)$$

which is threefold the value

$$E(L_s \gg 1) = KT. \quad (34)$$

To see the range of validity of Hooke's law we introduce instead of the relative length L the extension or strain $\epsilon = L - 1$. (31) becomes thus

$$Z = KT \left[(1 + \epsilon) - \frac{1}{(1 + \epsilon)^2} \right] = 3KT \cdot \epsilon \left[1 - \epsilon + \frac{4}{3}\epsilon^2 - \dots \right] \quad (35)$$

From (35) it follows that for extensions as small as 5 per cent there is a 5 per cent deviation from Hooke's law. Young's modulus is, of course, the same for both variables L and ϵ as reference.

Nominal Versus True Stress-Strain Curve

Equation (31) represents a *nominal* stress-strain curve, *i.e.*, the stress is the force referred to unit original cross-section. The *true* stress-strain curve for which the stress is referred to the actual cross-section may be simply obtained from (31) using (25). Designating the true stress

$$\xi = Z \cdot L \quad (36)$$

we have

$$\xi = KT \left[L^2 - \frac{1}{L} \right] \quad (37)$$

Young's modulus is now defined:

$$E_T(L) = \frac{d\xi}{dL} = KT \left[2L + \frac{1}{L^2} \right], \quad (38)$$

and has the values

$$\begin{aligned} E_T(1) &= 3KT \\ E_T(L \gg 1) &= 2KT \cdot L \end{aligned} \quad (39)$$

for $L = 1$ and large L respectively.

In terms of the strain ϵ the equation (37) reads:

$$\xi = KT \left[(1 + \epsilon)^2 - \frac{1}{1 + \epsilon} \right] = 3KT \epsilon \left[1 + \frac{\epsilon^2}{3} - \frac{\epsilon^3}{3} + \dots \right] \quad (40)$$

Thus, for the true stress-strain curve Hooke's law holds over a much wider range of strains than for the nominal stress-strain curve.

For metals in particular a true strain

$$\lambda = \int_1^L \frac{dL}{L} = \log L = \log(1 + \epsilon); L = e^\lambda; \epsilon = e^\lambda - 1 \quad (41)$$

is introduced usually instead of the nominal strain ϵ . In terms of ζ and λ as dependent and independent variables (40) takes on the form:

$$\zeta = KT[e^{2\lambda} - e^{-\lambda}] \quad (42)$$

Young's modulus is now in terms of λ :

$$E_f(\lambda) = \frac{d\zeta}{d\lambda} = KT[2e^{2\lambda} + e^{-\lambda}] \quad (43)$$

Therefrom

$$E_f(\lambda \gg 0) = 2KT \cdot e^{2\lambda} \quad (44)$$

Young's modulus for small extensions has the same value for the three pairs of variables as it should; for large values of the strain, however, the moduli differ from one another.

Instead of λ one uses sometimes the logarithm of the reduction in area to measure the strain, because for metals in the stage of necking the strain is not directly observable. For rubber, because of its incompressibility, the logarithm of the reduction in area is simply the reciprocal of the true strain.

We introduced here true stress and true strain because it is instructive to compare analytically the expressions for stress and strain in the three different pairs of variables. It is obvious that in the range of stress and strain in which the volume of rubber does not change with extension, there is no advantage in using a true stress-strain curve instead of a nominal one.* The situation is different when rubber crystallizes, particularly when necking takes place before breaking. Then the use of the true stress-strain, or rather true stress vs. reduction in area curves probably will offer the same advantages over the nominal stress-strain curves as in the case of metals.

The Thermoelastic Effects for the New Model

For the rise in temperature on fast stretching insertion of (31) in (11) yields:

$$\Delta T = \frac{KT}{2C_L} [L_s^3 + L_s - 2] \left[\frac{L_s - 1}{L_s} \right] \quad (45)$$

The linear thermal expansion coefficient parallel to the direction of the stress α_{\parallel} (L_z) becomes:

$$\alpha_{\parallel}(L_s) = \frac{1}{L_s} \left(\frac{\partial L_s}{\partial T} \right)_z = -\frac{1}{T} \frac{L_s^3 - 1}{L_s^3 + 2} \quad (46)$$

This expression does not differ significantly from (15) to which it reduces for $L_z \gg 1$. A novel feature, however, is the possibility of computing the linear thermal expansion coefficient perpendicular to the direction of the stress:

$$\alpha_{\perp}(L_s) = \frac{1}{L_y} \left(\frac{\partial L_y}{\partial T} \right)_z = \frac{1}{2T} \frac{L_s^3 - 1}{L_s^3 + 2} \quad (47)$$

In deriving (47) the constancy of the volume of rubber during stretching, *i.e.*, the relation (25), was used. The possibility of introducing $\alpha_{\perp}(L_z)$ rests on the three-dimensional character of the new network model in contrast to the essentially one-dimensional bundle model.

The formulas (46) and (47) still do not contain the cubic expansion coefficient of unstretched rubber and consequently do not show a thermoelastic inversion point.

* In addition the area under the nominal stress-strain curve has a simple thermodynamical meaning: it represents the work done by the stretching force.

Generalization of the Stress-Strain Relation to Larger Extensions

The generalization of our model to larger extensions involves three parts:

(A) The contracting force for a single chain has to be generalized to hold beyond the range of validity of the Gaussian distribution.

(B) An irregular network has to be considered and reduced to a form in which the expression for the contracting force for a single chain may be utilized for the contracting force of the whole network.

(C) The contracting force of the network has to be balanced by the internal pressure of the rubber liquid and any external forces.

The result for part (A), the contracting force for a single chain, was recorded earlier. Part (B) could not be treated in the same rigorous fashion as was possible for the Gaussian chains. Instead of carrying out the reduction from an irregular to a regular network, we simply assume that in the unstretched state of the material each independent chain is taken to have an extension equal to κ times its maximum length. The maximum stretch is thus given by a factor $1/\kappa$, a quantity which will depend upon the constitution of the particular rubber considered. κ is an adjustable parameter in our treatment.

Considering again the equilibrium of forces and using for the contracting force the three-dimensional result (23)

$$Z = K'T \left[\mathcal{L}^{-1}(L_e \kappa) - \frac{3\kappa}{L_e^2} \right] \quad (48)$$

This relation involves essentially two parameters, the scale factor K' and the new maximum stretch parameter κ . When the extension is small compared to the maximum

$$\mathcal{L}^{-1}(t) \cong 3t \quad (49)$$

$$Z \cong 3\kappa K' \left[L_e - \frac{1}{L_e^2} \right] \quad (50)$$

i.e., (48) reduces to the Gaussian expression (31), $3\kappa K'$ taking the place of the old parameter K .

Equation (48) yields an S-shaped stress-strain curve. The occurrence of the inflexion point, *i.e.*, of the S-shape, is explained as due to the superposition of the effects of the contracting force and those of the internal pressure.

Referred to the actual cross-section the nominal stress-strain relation (48) assumes the form:

$$Z = K'T \left[L_e \mathcal{L}^{-1}(L_e \kappa) - \frac{3\kappa}{L_e} \right] \quad (51)$$

This true stress-strain curve does *not* show the S-shape of the nominal stress-strain curve. Fig. 6 curve A shows the true stress versus nominal relative length curve corresponding to the nominal curve B. The S-shape of curve B is well explained by equation (48), and the shape of curve A by equation (51).

Influence of the Thermal Expansion on the Stress-Strain Relation

With the successive refinements introduced we were able to explain the peculiar thermoelastic properties of rubber, except the thermoelastic inversion point. To explain this phenomenon we have to take into account the cubic thermal expansion of unstretched rubber, characterized by a coefficient of thermal expansion α defined as

$$V(T) = V(T_0)[1 + \alpha(T - T_0)] \quad (52)$$

FIGURE 6. Curve A. True stress vs. nominal relative length for an accelerated pure gum stock. Curve B. Nominal stress vs. nominal relative length corresponding to Curve A. The circles are theoretical values according to Equation (31). The dashed line represents the asymptote of the theoretical curve.

The previous stress-strain relation (31) yields zero stress for $L = 1$, the unstretched state. When thermal expansion is considered, the unstretched state is characterized

by $L = 1 + \frac{\alpha}{3}(T - T_0)$

The previous equation (31) should be changed to

$$Z = KT \left[L - \frac{1 + \alpha(T - T_0)}{L^2} \right] \quad (53)$$

which gives $Z = 0$ at $L = 1 + \frac{\alpha}{3}(T - T_0)$. The thermal expansion enters only into the internal pressure term, and the contracting force (the first term in the bracket) is independent of α . We emphasize that L by definition is independent of α , the original length being taken at $T = T_0$.

Equation (53) predicts a thermoelastic inversion point as the solution of the equation

$$\left(\frac{\partial Z}{\partial T} \right)_L = K \left[L - \frac{1 + \alpha(2T - T_0)}{L^2} \right] = 0. \quad (54)$$

Thus, the critical extension at which the stress-temperature curves, the isometrics, change their slope, is given by the isometric thermoelastic inversion point

$$L^3_{iso} = 1 + \alpha(2T - T_0) = 1 + \alpha T_0; \text{ for } T = T_0, \quad (55)$$

Because of the thermodynamic relation

$$\left(\frac{\partial L}{\partial T}\right)_Z = -\left(\frac{\partial L}{\partial Z}\right)_T \left(\frac{\partial Z}{\partial T}\right)_L \quad (56)$$

the isotonic thermoelastic inversion point is identical with the isometric one.

From (52) and (56) the linear thermal expansion coefficients in the direction of the stress and perpendicular to it: $\alpha_{||}$ and α_{\perp} may be computed. One obtains for $T = T_0$

$$\alpha_{||}(L_z) = \frac{1}{L_z} \left(\frac{\partial L_z}{\partial T}\right)_Z = -\frac{1}{T} \frac{L_z^3 - 1}{L_z^3 + 2} + \frac{\alpha}{L_z^3 + 2}, \quad (57)$$

and

$$\alpha_{\perp}(L_z) = \frac{1}{L_y} \left(\frac{\partial L_y}{\partial T}\right)_Z = +\frac{1}{2T} \frac{L_z^3 - 1}{L_z^3 + 2} + \frac{\alpha}{2} \frac{L_z^3 + 1}{L_z^3 + 2}. \quad (58)$$

In deriving (58) the constancy of the volume of rubber during stretching was used:

$$V = L_y^2 L_z = 1 + \alpha(T - T_0) \quad (59)$$

In the unstretched state $L_z = 1$ we have

$$\alpha_{||}(1) = \alpha_{\perp}(1) = \alpha/3, \quad (60)$$

as for any isotropic material. $\alpha_{||}$ changes from positive to negative values with increasing L_z , whereas α_{\perp} always stays positive.

The formula corresponding to equations (12) and (45) becomes for $\alpha \neq 0$:

$$\Delta T = \frac{KT}{2CL} \left[L_z^2 + L_z - 2(1 + \alpha T_0) \right] \left[\frac{L_z - 1}{L_z} \right] \quad (61)$$

According to this formula ΔT starts with the value zero at $L_z = 1$, reaches a minimum for $L_z = L_{iso}$ as given by (55), then becomes zero for the adiabatic thermoelastic inversion point, determined by

$$L_{ad}^2 + L_{ad} - 2(1 + \alpha T_0) = 0 \quad (62)$$

and takes on positive values for $L_z > L_{ad}$. (57) and (61) explain Joule's data in Figs. 2 and 1.

The introduction of the cubic thermal expansion of rubber into the stress-strain relation (51) is simple, because only the internal pressure is modified. One obtains:

$$Z = K'T \left[\mathcal{L}^{-1}(L_z \kappa) - \frac{3\kappa[1 + \alpha(T - T_0)]}{L_z^2} \right] \quad (63)$$

Comparison of the Theoretical Stress-Strain Relations with Experiment

In comparing the theory with experiment, a resolution of the stress into its additive parts due to entropy and internal energy has to be carried out both for the experimental results and for the theory.

In van der Waals' equation of a real gas

$$p = -\frac{a}{V^2} + \frac{R}{V-b} T \quad (64)$$

the first term $p_{(U)} = -a/V^2$ is due to the internal energy U and the second term $p_{(S)} = RT/(V-b)$ is due to entropy S . According to thermodynamics:

$$p_{(U)} = -\left(\frac{\partial U}{\partial V}\right)_T, \quad p_{(S)} = T\left(\frac{\partial S}{\partial V}\right)_T = T\left(\frac{\partial p}{\partial T}\right)_V \quad (65)$$

so that

$$p = p_{(V)} + p_{(S)} = -\left(\frac{\partial U}{\partial V}\right)_T + T\left(\frac{\partial p}{\partial T}\right)_V \quad (66)$$

For a unilateral stress Z instead of a uniform pressure p we have to replace p by $-Z$ (since pressure and stress act in opposite directions) and the volume V by the relative length L . Then we obtain

$$Z = Z_{(V)} + Z_{(S)} = \left(\frac{\partial U}{\partial L}\right)_T + T\left(\frac{\partial Z}{\partial T}\right)_L \quad (67)$$

Using equation (67) we may deduce experimental $Z_{(V)}$ and $Z_{(S)}$ curves plotted versus L from any experimental stress-strain curve. The theoretical $Z_{(V)}$ and $Z_{(S)}$ vs. L curves follow from (53) and (63) by the help of (67):

$$Z_{(V)} = \alpha K T^2 L_s^{-2}; Z_{(S)} = K T \{ L_s - [1 + \alpha(2T - T_0)] L_s^{-2} \} \quad (68)$$

$$Z_{(V)} = 3K'\kappa\alpha T^2 L_s^{-2}; Z_{(S)} = K'T \{ \mathcal{L}^{-1}(L_{zK}) - 3\kappa[1 + \alpha(2T - T_0)] L_s^{-2} \} \quad (69)$$

(69) we compare with experimental results obtained by Anthony, Caston and Guth. Fig. 7 is taken from a paper by James and Guth which appeared in the *Journal of Chemical Physics* in Oct. 1943. The over-all agreement between theory and experiment is rather good, except at the lowest extensions where van der Waal's forces, neglected in the theory, may play a role. For further comparisons between theory and experiment we refer to Section 7 of the paper by James and Guth and to the papers by the author and his associates.²

Concerning the molecular interpretation of the two constants κ and K' of the theory we must refer to the paper by James and Guth. There the new concept of the fraction of the chains actively involved in the network is introduced in contrast to the old concept of the molecular weight.

Limitations of the Theory

The theory of James and Guth does not consider crystallization phenomena which are not essential for the occurrence of rubber-like elasticity. In fact it is known that Buna S (GR-S) type synthetic rubber, though it does not crystallize, still exhibits the characteristic S-shape in its stress-strain curve. The unaccelerated pure gum stock of Fig. 7 also does not show crystallization up to about 400 per cent extension, while revealing an S-shape.

It is not possible to develop a theory of the crystallization of rubber-like materials as general as our theory of rubber elasticity. The magnitude and geometrical distribution of the intermolecular forces regulating crystallization will depend greatly upon the chemical composition of the elastomer.

One may consider how the average molecular weight or chain length and the chain length distribution curve of milled rubber in solutions will influence the elasticity of the cured product. In our theory this effect will be evident in the constants κ and K' . The amount of branching or cross-linking may similarly be treated.

It should be pointed out that the theory of James and Guth provides a basis for the explanation of many other physical properties of stretched rubber.

General Occurrence of Rubber-like Materials

According to the principles advanced in our theory, any long-chain compound with free rotation will exhibit rubber-like elasticity above its melting point. Conversely, any compound exhibiting rubber-like elasticity will be a long chain compound possessing free rotation. Long-chain compounds have a melting point or melting range above which there is free rotation. Whether this melting point is be-

FIGURE 7. Internal energy and entropy contributions to the stress for an unaccelerated pure gum compound. The circles are theoretical values according to the equation (63).

low or above room temperature depends on the competition between free rotation and molecular forces. The free rotation may be started either by raising the temperature or by introducing a solvent either by plasticizing or swelling. A survey of rubber-like materials was given by the author in another paper.¹² Here we restrict ourselves to a few examples:

(a) gutta-percha, the trans-isomer of rubber, shows rubber-elasticity above 70° C;

(b) the inorganic substances sulfur, selenium, phosphorus chloronitride, and sulfur trioxide possess elastic modifications at higher temperatures and under special circumstances;

(c) synthetic elastomers, like neoprene, butyl rubber, thiokol and the butadiene types; synthetic linear polymers¹³;

(d) polystyrene, polyindene and allied substances;

(e) cellulose derivatives;

(f) nylon;

(g) biological materials, like gelatin, glue, wool, silk, and the muscles.

SUMMARY

Fundamental facts on the elasticity of rubber are the thermoelastic effects and the S-shape of the stress-strain curve with its continuation for compression. There are three thermoelastic phenomena for elastomers:

- (1) They exhibit a rise in temperature on fast stretching.
- (2) If stretched by a constant load (*i.e.*, isotonically) they contract visibly when heated.
- (3) The stress in an elastomer kept at constant extension (*i.e.*, isometric stretch) increases with rising temperature.

These three effects are correlated by thermodynamics.

The theory of James and the author explains quantitatively all these fundamental facts on rubber elasticity. It explains observed finer details of thermoelasticity. The change in temperature on fast stretching is negative (cooling) for low extensions, passes through a minimum, becomes zero (adiabatic thermoelastic inversion point), and finally assumes positive values (heating) for increasing extensions. It explains the observed thermal anisotropy of isotonically stretched rubber. The linear thermal expansion coefficient is negative in the direction of the stress but positive in the direction perpendicular to the stress. Both for isotonic and isometric stretch there exists a thermoelastic inversion point which is about half of the value of the critical extension for the adiabatic thermoelastic inversion point. The visible contraction of isotonically stretched rubber when heated is due to the fact that the negative linear thermal expansion coefficient of stretched rubber is of the magnitude of the (cubic) thermal expansion coefficient for a gas. The thermoelastic inversion points are determined in a simple manner by the cubic thermal expansion coefficient of unstretched rubber. The S-shape of the stress-strain (compression) curve is also explained by the theory.

The thermoelastic effects (except the inversion phenomena) may be explained on the basis of the bundle model introduced earlier by the author. In this model bulk rubber is assumed to consist of a bundle of parallel strings built up from flexible (free rotation) long chain molecules. However, only the new network model by James and the author can explain the stress-strain curve at low extensions and its continuation for compression. This model is also needed to explain the thermal anisotropy of stretched rubber. The inversion phenomena, finally, may be explained by taking into account the cubic thermal expansion of unstretched rubber.

In the discussion of the structure of bulk rubber, a brief account is given of the theory of gelation by Flory. The question of nominal versus true stress-strain curves is discussed. In the range of strains for which the volume of stretched rubber remains constant, no advantage is gained by using the true stress-strain curve. However, if the volume changes and particularly in the stage of necking before breaking, the true stress versus reduction in area curve may offer similar advantages as in the corresponding case of metals.

APPENDIX

Finite Flexible Chains in One and Three Dimensions

We consider a chain of N links, each of which has the probability of $1/2$ of contributing $+l$ or $-l$ to the net length L of the chain. If N_+ represents the number of links contributing a length $+l$, to the net length and N_- the number of links contributing a length $-l$, the probability that we have N_+ links in one direction and N_- links in the other is

$$C(N_+, N_-) = \left(\frac{1}{2}\right)^N \frac{N!}{N_+! N_-!} \quad (I)$$

It is obvious that $N_+ + N_- = N$ and that the net length of the chain will be $L = l(N_+ - N_-)$. Solving for N_+ and N_- in terms of L we obtain as the probability distribution for a given length L

$$C(L, N) = \left(\frac{1}{2}\right)^N \cdot \frac{N!}{\left(\frac{N + L/l}{2}\right)! \left(\frac{N - L/l}{2}\right)!} \quad (\text{II})$$

Using Stirling's approximation, we have

$$N! = N^N e^{-N} \sqrt{2\pi N} \quad (\text{III})$$

and equation (II) becomes, writing $t = L/Nl$,

$$C(L, N) = \frac{2}{(2\pi N)^{1/2}} (1+t)^{-\frac{n}{2}(1+t)} (1-t)^{-\frac{n}{2}(1-t)} (1-t^2)^{-1} \quad (\text{IV})$$

This reduces to equation (18) of the text if we neglect the slowly varying factor $(1-t^2)^{-1/2}$

The occurrence of the function

$$t = \tanh f \quad (\text{V})$$

in equation (22) of the text may be made plausible by observing the analogy of our problem with Ehrenfest's problem of the orientation of a magnetic particle capable only of two (parallel and antiparallel) positions with regard to an external magnetic field. According to the Maxwell-Boltzmann relation the average length \bar{l} of a link l on which a stress Z acts is then, for our one-dimensional chain,

$$\bar{l} = l \frac{e^f - e^{-f}}{e^f + e^{-f}} = l \tanh f; f = \frac{Zl}{kT} \quad (\text{VI})$$

Noting that $\bar{l}/l = t$, equation (VI) reduces to (V).

The occurrence of the Langevin function for the three-dimensional flexible chain may be explained similarly. For this chain the projections of each link may take on continuously all values between $-l$ and $+l$. The Maxwell-Boltzmann relation then yields.

$$\bar{l} = \frac{\int_0^\pi \exp\left[\frac{lZ \cos \theta}{kT}\right] l \cos \theta \sin \theta d\theta}{\int_0^\pi \exp\left[\frac{lZ \cos \theta}{kT}\right] \sin \theta d\theta} \quad (\text{VII})$$

where θ is the angle between the directions of l and Z . Equation (VII) yields

$$\bar{l} = l \left(\coth f - \frac{1}{f} \right) = l \mathcal{L}(f) \quad (\text{VIII})$$

This three-dimensional problem is completely analogous to the orientation of polar molecules in an electric or magnetic field. The thermal agitation of the chain (characterized by kT) tends to disorient the links and make the average component in the direction of the stress vanish. The tension Z in the chain tends to orient the links.

The Vitreous State

MAURICE L. HUGGINS AND KUAN-HAN SUN

Eastman Kodak Co., Rochester, N. Y.

and

ALEXANDER SILVERMAN

Department of Chemistry, University of Pittsburgh, Pittsburgh, Pa.

General Considerations

If a substance possesses a degree of rigidity comparable to that possessed by typical crystalline substances, yet lacks the dependence on direction (characteristic of the crystalline state) of such properties as hardness, rate of growth and solution, and (sometimes) refractive index, it is said to be in the vitreous* state.†

From the structural point of view, the vitreous state of matter may be defined, alternatively, as that state in which the arrangement of the component atoms, ions, or molecules possesses a *permanence* similar to that in the crystalline state and a *randomness* similar to that characteristic of liquids.

The terms *vitreous substance*, *vitreous solid*, *amorphous solid*, *supercooled liquid*, *glass*, and *plastic* may be considered to be practically synonymous. The term used by a given author at a given time is largely a matter of preference, depending in part on the type of characteristic property (*e.g.*, rigidity, lack of directional proper-

* Vitreous is a derivative of the Latin "vitreus," itself derived from "vitrum," which means "glass." [Incidentally, because of their glassy appearance the sulfates of zinc, copper and iron were called respectively white, blue and green vitriol. The acid distilled from green vitriol was called oil of vitriol, or commonly "vitriol." See "The Natural History of C. Plinius Secundus," translation by K. C. Bailey, p. 180, London, 1932. J. A.]

† Certain properties (*e.g.*, the refractive index) of crystals belonging to the cubic (isometric) system are independent of direction. Macroscopic properties of substances which are microcrystalline, such as many metals as ordinarily produced, may also apparently be the same for all directions, the measured properties being averages or summations of the properties of the individual randomly oriented "crystallites."

ties, method of production) which it is desired to emphasize. For example, industrial usage distinguishes between glasses and solid organic plastics, on the basis of characteristic differences in hardness.

A rigorous definition of a vitreous substance is impossible, without the introduction of purely arbitrary quantitative limiting values for the rigidity (or viscosity) and the dependence of various properties on direction or for the degree of permanence and lack of order in the atomic distribution. Rather than to introduce such arbitrariness, it seems better to consider the term *vitreous* merely as a convenient descriptive adjective, realizing that there are many borderline cases to which it may be applied or not, as convenient.

On raising the temperature, most vitreous solids are transformed to liquids; the transformation, however, is a gradual one, whereas change from the crystalline state to the liquid state is sharp.* A vitreous substance in the transition range has properties intermediate between those characteristic of an amorphous solid and of a liquid. It may be described either as a very viscous liquid or as a plastic solid, as suits one's fancy. Tars are typical examples of vitreous substances whose transition range is at ordinary temperatures. The transition ranges for thermoplastic resins, for example, are somewhat above, and for common silicate glasses very much above, ordinary room temperatures.

Gels, consisting of a more or less rigid, high-molecular framework with interspersed small molecules, each in much the same state as in a liquid, are also intermediate between the vitreous and liquid states, though in a somewhat different sense.

As examples of substances intermediate between vitreous and crystalline solids, one may mention glasses which are inhomogeneous and show a tendency toward crystallization, and also organic long-chain polymers which have been given directional properties by stretching or cold-drawing.

Stretched rubber or other elastic substances may be considered to be intermediate between the vitreous, crystalline, and liquid states. As regards its rigidity, it is intermediate between a liquid and a vitreous solid. It has, to a limited extent, the directional properties characteristic of the crystalline state.

Looking at the subject from an atomic point of view, the reasons for the existence of many borderline cases are obvious. Like atoms (or ions or groups of atoms) tend to be surrounded by other atoms (or ions or atomic groups) in a like manner. In any condensed system—crystalline solid, vitreous solid, or liquid—there tends to be a regularity in the local atomic distribution immediately surrounding each atom (or ion or group of atoms). Thus, in all silicate crystals of known structure and presumably also in silicate glasses, each silicon atom is tetrahedrally surrounded by four oxygen atoms at a distance of about 1.6 Å, and each oxygen has adjacent to it either two silicon atoms or one silicon and one or more atoms of another element or elements. If, in addition to the local regularity, there is also a long-distance regularity, the substance is crystalline; if not, it is a vitreous solid or a liquid, depending on the degree of permanence of the long-distance structure—a function of temperature.

A crystalline arrangement of atoms or molecules has (nearly always, at least) a lower energy than a non-crystalline arrangement, although the difference is usually not large. If the interatomic (or interionic or intermolecular) forces tending to maintain a momentarily existing long-distance structure are small enough, the thermal vibrations of the atoms will cause the structure to change rapidly to a different one: the substance is a liquid. If the substance is then cooled rapidly to a temperature such that the average kinetic energy tending to change the structure is considerably smaller than the energy humps tending to prevent rearrangement to a

* Except in substances which show mesomorphic states. See paper by G. Friedel in Vol. I of this series. J. A.

crystalline structure, a vitreous solid results. If, on the other hand, the cooling takes place sufficiently slowly, and if the energy of a structure having long-distance regularity is enough lower than the energy of any other structure, a crystalline substance is produced. The existence of vitreous substances is thus closely related to the strengths of the interatomic, interionic, and intermolecular forces and to the rate of cooling from the liquid state.

In general, a substance tends to be a solid if interatomic bonds, strong enough successfully to resist breaking by thermal collisions, form a three-dimensional network structure extending throughout the mass. If a *regular* network structure has a considerably lower energy than any *irregular* structure, the solid tends to be crystalline. If, however, different arrangements have practically equal energy, it tends to be amorphous. For example, long-chain polymers having occasional cross-links (or strong interchain forces) between the chains tend to be amorphous, because different orientations around each of the single bonds in the chains have nearly the same energy and so are almost equally probable. Moreover, if the distribution of crosslinks is a random one, as is usually the case, regularity of structure is impossible.

Similar considerations apply to silicate glasses. The strongest interatomic forces in these are usually between adjacent silicon and oxygen atoms. Because of these forces, as already noted, each silicon is bonded tetrahedrally to four oxygens, and each oxygen either to *two* silicons (the angle between the bonds being roughly the "tetrahedral" angle) or to *one* (usually in addition to one or more other metallic atoms). In most ordinary glasses, the ensemble of Si-O bonds forms a network structure. The rings, of which this network may be considered to be composed, are of various sizes—partly because of the effects of the other atoms, of various sizes and coordination numbers, and partly because the energy of the network depends only very slightly on the ring-size distribution (See Fig. 1). The fact that different

FIGURE 1. Two-dimensional representations of crystalline (a) and vitreous (b) SiO_2 structures (after Zachariasen⁴⁷ and Warren⁴¹).

relative orientations of practically equal stability are possible for the two Si-O bonds extending from many of the oxygen atoms contributes both to the irregularity of distribution of ring sizes and to the irregularity in shape of the rings of the same size.

A polyhydroxy small molecule compound, such as glucose, tends to be vitreous, when solid, both because the intermolecular hydrogen bridges are of nearly equal strength, regardless of which oxygen atoms are connected by them and regardless

of the O—H · · · O angle (within limits), and because different orientations of each O—H (or O · · · H) bond, relative to the adjacent C—O bond, give nearly equal stability.

All of the substances which we consider amorphous, both liquids and solids, possess some degree of order—at least the already-mentioned approximate regularity of arrangement around each kind of atom and approximate uniformity of corresponding interatomic distances, bond angles, etc. Order over somewhat larger distances also exists, in many cases at least, although macroscopic properties give no direct evidence of this on account of the randomness of orientation of the small regions (usually of colloidal dimensions) possessing this order. The permanence or evanescence of short-range order and intermediate-range order depends largely on the strengths of the interatomic forces involved and on the temperature.

Crystalline substances often possess some degree of disorder; to the extent that this is the case, they are not perfectly crystalline. Foreign atoms (impurities) and vacant atomic sites may be distributed irregularly throughout the structure. "Crystallographically equivalent" positions may be occupied irregularly by atoms of two or more kinds^{3, 4, 5, 40} (in many "solid solutions"). Twinning may occur, producing differences of crystal orientation in adjacent portions of the structure. The orientations of certain atomic groups (*e.g.*, in organic molecules) in a crystal may be more or less random, even though the distribution and orientation of the molecules as a whole is regular.³² Atomic groups and even whole molecules may, in fact, be continuously rotating in the crystal.^{33, 38} Strictly speaking, also, there is a randomness in the instantaneous distribution of atoms in any crystal, resulting from their temperature vibrations and rotations.

Some Semiquantitative Considerations

Most of the temperature motions of the atoms in any solid or liquid can be considered as oscillations (not mutually independent) about equilibrium positions. In addition to the changes of relative atomic positions resulting from these oscillations, larger changes may occur, in which the energy (strictly, the *free* energy²⁵) of the system first increases and then decreases; an energy hump is passed over. In many instances the change taking place can be (approximately) described very simply, *e.g.*, as a shift of position of a single atom or a shift of position or of orientation of a group of atoms, even though smaller displacements of other neighboring atoms must necessarily occur concurrently.

Each rearrangement of this sort is characterized by two important energy quantities: (1) the difference (ΔE) between the energy of the system before the change and that after the change, and (2) the magnitude of the energy hump passed over, *i.e.*, the difference between the energy of the system before the change and its maximum energy at any time during the change (See Fig. 2).

The latter quantity is called the "activation energy" for the change; we shall designate it as E_{a1} for a change from a lower energy state (1) to a higher state (2) and as E_{a2} for a change from a higher energy state to a lower. Obviously,

$$\Delta E = \pm (E_{a1} - E_{a2}), \quad (1)$$

the plus sign applying to the change from state 1 to state 2, the minus sign to the reverse change.

Generally speaking, amorphous substances are those for which many internal changes of this sort are possible, with ΔE small in magnitude. This statement will now be amplified and put on a semiquantitative basis.

If, for a given atomic shift or rearrangement, states 1 and 2 are in thermodynamic equilibrium with each other (but not with any additional states), it can be shown that the probability that the system is in state 1 is

FIGURE 2. Illustrating certain energy relationships pertaining to a structural rearrangement in a solid or liquid.

$$P_1 = \frac{e^{\Delta\epsilon}}{1 + e^{\Delta\epsilon}}, \quad (2)$$

where

$$\Delta\epsilon = \frac{|\Delta E|}{k'T}, \quad (3)$$

T being the absolute temperature and k' being a constant depending on the Boltzmann constant (k) and also on the number of atoms making the shift and the tightness with which these atoms are bound to each other and to neighboring atoms, *i.e.*, the independence of their oscillational motion. For the purpose of this discussion, k' can be considered to have a uniform, constant value, approximately equal to k .

The probability that the system is in state 2 is

$$P_2 = 1 - P_1 = \frac{1}{1 + e^{\Delta\epsilon}} \quad (4)$$

Figures 3 and 4 show the variation of P_1 and P_2 with $\Delta\epsilon$ and with T (for a constant $\Delta E/k'$). The greater the energy difference, at a given temperature, the

FIGURE 3. The probabilities of two states, in equilibrium with each other, as functions of $\Delta\epsilon$. The probability of the simultaneous existence of 1000 independent subsystems (all having the same value of $\Delta\epsilon$) is also shown (dotted line).

FIGURE 4. The probabilities of two states, in equilibrium with each other, as functions of the absolute temperature, assuming $\Delta E/k'$ constant (equal to 600 or 2000, as indicated). The probabilities of the simultaneous existence in state 1 of 1000 independent subsystems are also shown (dotted lines).

greater is the probability that the system is in the lower energy state. The higher the temperature, for a given value of $\Delta E/k'$, the more nearly equal are the probabilities for the two states.

If a given sample of the substance under consideration contains a large number of small subsystems, each of which can have two or more atomic distributions differing in energy by the same amount (or, more precisely, by the same value of $\Delta E/k'$, the probabilities just discussed and represented in Figures 3 and 4 are equal to the fractions of these subsystems which are in the respective states at a given instant, provided there is thermodynamic equilibrium.

A substance of this sort should be considered crystalline only if (practically) all of the subsystems throughout relatively large regions, containing many thousands of atoms, have the same atomic distribution—normally that (state 1) having the lowest energy. The probability that a mole of the substance is crystalline is (practically) P_1^n , n being the number of subsystems, of the sort just discussed, in the mole. The dotted curves in Figs. 3 and 4 show how P_1^n varies with $\Delta \epsilon$ and with T , for $n = 1000$. It is obvious that with very large values of n , a crystalline structure is very improbable, unless $\Delta \epsilon$ is large.

The change of entropy (per mole) accompanying crystallization, for the sort of substance being discussed, is

$$\Delta S_c = S_c - S_v \approx k \ln P_1^n - k \ln (1 - P_1^n) \approx kn \ln P_1. \quad (5)$$

The molal change in heat content—equal to the change in energy if there is no volume change—accompanying crystallization is

$$\Delta H_c = \Delta E_c = E_c - E_v = -nP_2 \Delta E. \quad (6)$$

The free energy change associated with crystallization is therefore

$$\Delta F_c = F_c - F_v = \Delta H_c - T\Delta S_c \approx -nP_2 \Delta E - nkT \ln P_1. \quad (7)$$

Fig. 5 shows the manner in which the free energy of crystallization varies with the temperature, according to this equation and Equations (2), (3), and (4).

FIGURE 5. Dependence of the free energy of crystallization on the absolute temperature, according to Eq. (7), assuming $n \Delta E = 200$ cal and 1000 cal, with $k' = k$ and $n =$ Avogadro's number in both cases.

The temperature at which $\Delta F_c = 0$ is that below which the crystalline state is more stable than the amorphous, and above which a noncrystalline distribution is the more stable. This temperature is the melting point of the crystalline material, if the viscosity of the noncrystalline substance at that temperature is sufficiently low for it to be liquid.

It should be emphasized that the foregoing discussion applies only to a substance in a state of thermodynamic equilibrium. The rate at which the equilibrium state is approached and the viscosity of the amorphous material both depend primarily, not on the energy difference (ΔE) between more or less stable states, but on activation energies (E_{a1} and E_{a2}) which may be much larger than the ΔE values.

Neglecting certain minor considerations, the rate of change from state 1 to state 2 (or from 2 to 1) is proportional to the number of subsystems in state 1 (or state 2) and to $e^{-\epsilon_1}$ (or $e^{-\epsilon_2}$), where ϵ_1 and ϵ_2 are defined by the equations

$$\epsilon_1 = \frac{E_{a1}}{k'T} \quad (8)$$

and

$$\epsilon_2 = \frac{E_{a2}}{k'T} \quad (9)$$

If we denote by f_2 the instantaneous fraction of subsystems in state 2 at time t , by $f_{2,0}$ the fraction in this state at $t = 0$, and by $f_{2,\infty}$ that fraction at $t = \infty$ (i.e., at equilibrium), the net rate of change of f_2 can be shown to be

$$\begin{aligned} \frac{df_2}{dt} &= k''(f_{2,\infty} - f_{2,0})(e^{-\epsilon_2} + e^{-\epsilon_1})\exp[-k''(e^{-\epsilon_2} + e^{-\epsilon_1})t] \\ &= k''(f_{2,\infty} - f_{2,0})(1 + e^{-\Delta\epsilon})\exp[-\epsilon_2 - k''e^{-\epsilon_2}(1 + e^{-\Delta\epsilon})t] \end{aligned} \quad (10)$$

A similar relationship holds for df_1/dt . For our present purpose, k'' can be considered merely as another constant.

If $\Delta\epsilon$ is not too small, $e^{-\Delta\epsilon}$ can be neglected relative to unity; then

$$\frac{df_2}{dt} = k''(f_{2,\infty} - f_{2,0})\exp[-\epsilon_2 - k''e^{-\epsilon_2}t]. \quad (11)$$

For the actual fraction, f_2 , at time t , the relation (also for $\Delta\epsilon$ not too small) is

$$f_2 = f_{2,\infty} + (f_{2,0} - f_{2,\infty})\exp[-k''e^{-\epsilon_2}t]. \quad (12)$$

In place of Equation (11), we may therefore write

$$\frac{df_2}{dt} = k''(f_{2,\infty} - f_2)\exp[-\epsilon_2]. \quad (13)$$

Figure 6 shows the dependence of the net rate of change from state 2 to state 1

FIGURE 6. Dependence of the net rate of change from state 2 to state 1 on the magnitude of ϵ_2 , according to Eq. (13). (The units are arbitrary.)

on the magnitude of ϵ_2 , according to Equation (13). The scale is arbitrary, depending on the magnitude of $k''(f_{2,\infty} - f_2)$ at the time being considered. At constant temperature, the rate is seen to vary greatly with the magnitude of the activation energy E_{a2} (or, better, with E_{a2}/k').

Fig. 7 shows the very great dependence of the net rate of change from state 2 to state 1 on the temperature, for a constant value of E_{a2}/k' .

Fig. 8 shows the manner in which the fraction of subsystems in the upper energy state varies with time, for various values of $k''\epsilon_2$, according to Equation (12). The

FIGURE 7. Dependence of the net rate of change from state 2 to state 1 on the absolute temperature, for a constant value of E_{a2}/k' , according to Eq. 13. (The units are arbitrary.)

FIGURE 8. Variation with time (in arbitrary units) of the fraction of subsystems in the upper energy state (2), for various values of k''/ϵ (indicated by the numbers alongside the curves), according to Eq. (12).

different curves again illustrate the great dependence on the activation energy and the temperature of the rate at which the subsystems reach true stability (state 1).

In actual substances, there will, as a rule, be more than one type of structure shift, each characterized by two independent constants,

$$\frac{\Delta E}{k'} \text{ and } \frac{E_{a2}}{k'} \text{ (or } \frac{E_{a1}}{k'} \text{ and } \frac{E_{a2}}{k'} \text{ or } \frac{\Delta E}{k'} \text{ and } \frac{E_{a1}}{k'}).$$

These constants determine the relative fractions of the appropriate subsystems in the two energy states at equilibrium and the rate at which equilibrium is approached at any given temperature. A substance will be amorphous at a given temperature if there are considerable numbers of subsystems in energy states other than the lowest—which will be the case (at equilibrium) if $\Delta\epsilon$ is small for any (not too rare) type of structure shift. The substance will also be amorphous, even though equilibrium at the existing temperature would require practically all of the subsystems to be in their lowest energy states, if too rapid cooling from a higher temperature (at which many of the subsystems were in higher energy states) has so slowed the rates of the structure shifts as to prevent the attainment of equilibrium at the lower temperature.

Considerations similar to those above apply also to the theoretical treatment of viscosity. Without going into details, it may be mentioned that the viscosity is determined largely by the magnitudes of the energy humps (or, better, of the ratios $E_a/k'T$) which must be passed over as each small region of the substance shifts, in a given direction, relative to neighboring regions.

Let us now consider the state of affairs in a silicate glass of ordinary composition. The strongest interatomic forces are undoubtedly those between silicon and oxygen atoms. At ordinary temperatures, the ensemble of silicon and oxygen atoms is an irregular giant network (negatively charged). At sufficiently high temperatures, such as those at which the glass was made, the viscosity is that of an ordinary liquid; the network is continually being broken and re-formed, with a change of configuration. This necessitates the breaking and re-formation of Si-O bonds. Both the activation energy and the absolute temperature are large; the rate of the break-and-make process is determined chiefly by the ratio of the former quantity to the latter.

As the temperature is lowered, the rate of breaking of Si-O bonds rapidly becomes smaller and the viscosity greatly increases. Within the temperature range in which the viscosity is rapidly changing (or at any higher temperature), the structure existing at any instant is far from regular—because the differences in energy between different configurations (different sizes of rings, etc.) for each small region of the structure are small relative to the thermal energy available.

On further cooling, practically no Si-O bonds are broken; in this respect the structure remains fixed. Other changes, having smaller activation energies, continue to occur at temperatures somewhat below the range of rapid viscosity increase. These include the breaking and making of other metal-oxygen bonds and changes of orientation of Si-O bonds in the silicate net, insofar as possible without breaking any of these bonds or changing Si-O-Si bond angles too greatly from their most stable values. Those changes are preferred, over changes in the opposite direction, which result in a decrease in (free) energy.

If the cooling takes place very slowly through each temperature range in which the rate of shift, for a given type of structure change, is rapidly decreasing, approximate equilibrium, with respect to each of these types of changes, can be maintained. In those types of subsystems in which one of two alternative distributions is considerably more stable than the other, practically all will have the more stable distribution, when the temperature is reached at which the rate of shift becomes negligible. Slow cooling over all of these critical regions therefore produces a glass at room temperature which approaches the lowest possible energy—maximum stability. Rapid cooling through any of the critical regions results in the “freezing-in” of some relatively unstable atomic distributions. This results in strains and inhomogeneities. The tendency to relieve these strains, to give a thermodynamically more stable structure, produces slow internal changes persisting over a long period of time.

In general, a solid is much more readily fractured if its atoms are in a crystalline arrangement than if they are in an amorphous arrangement. The crystalline or

other atomic arrangement at and near the surface is especially important, since fracture nearly always starts from surface cracks. (Etching a glass surface usually increases the mechanical strength.) The "tempering" or "case-hardening" of vitreous products—sudden, uniform surface chilling from a temperature only slightly below the softening temperature—thus produces a uniformly amorphous surface region in which cracks are not readily started. The stability and other properties of the resultant product are of course very dependent on the temperature just before chilling, the rate and uniformity of chilling, etc.

Very slow cooling through temperatures only slightly below those at which the glass is fluid favors the production and growth of crystalline regions in the mass, the importance of this tendency being very greatly dependent on the composition, however. Such crystalline regions—especially if the crystal structure is quite anisotropic, with strength and other properties varying greatly with direction—may be very deleterious, producing inhomogeneity and other undesirable properties in the final product. On the other hand, the presence of many small crystalline regions in an amorphous matrix may make a glass artistically desirable, as in Aventurine glass (*e.g.*, "Goldstone").

Vitreous Sulfur and Selenium

In this and the following sections some typical substances and types of substances which form vitreous solids will be discussed, with emphasis on the structural relationships.

Among the elements known in the vitreous state are sulfur and selenium. According to the Lewis theory of valence and atomic structure,²⁶ a neutral atom of one of these elements has six valence electrons. It can complete a tetrahedral, four electron-pair valence shell by forming two single bonds—sharing two electron-pairs—with other atoms. (Double bonds are apparently unstable.) One would therefore expect these elements to form either rings or very long chains, each atom in either case (except for the few terminal atoms of the long chains) being bonded to two others, with a bond angle at least roughly approximating the tetrahedral angle ($\sim 110^\circ$). This expectation has been verified. The ordinary crystal forms of sulfur^{8, 44} and (probably) two of the crystal forms of selenium²⁴ contain 8-atom rings. Another crystal form of selenium^{6, 36} contains long helical chain molecules, extending completely through the crystal.

Amorphous sulfur and selenium can be obtained by rapidly cooling the liquids, after heating at a temperature sufficient to break the rings. These amorphous substances contain long chains of atoms²⁷ and probably also rings of various sizes, the chains and rings having many different configurations, because of the nearly equal stability of various orientations of each single bond relative to each of the two adjacent bonds. This picture is consistent with the rubberlike elasticity of amorphous sulfur at ordinary temperatures and of amorphous selenium at somewhat higher temperatures—a property now known to be due to the entropy decrease occurring when randomly kinked chains become more or less straightened out and mutually aligned, on stretching the material.^{9, 23, 28} The elasticity disappears as the temperature is lowered (as in the case of rubber) because the thermal motions of the atoms become insufficient to produce the changes of orientation at a sufficiently rapid rate.

Vitreous Silica

The structure of vitreous silica, SiO_2 , will next be discussed. Reasoning again from the Lewis theory of valence, it was concluded^{20, 26} that in silicon dioxide each silicon atom should be tetrahedrally bonded to four oxygen atoms and each oxygen should be bonded, by bonds making (approximately) tetrahedral angles with each other, to two silicons. These conclusions have been verified by the results of x-ray studies of quartz^{7, 13, 20, 45} and vitreous silica.^{42, 43} (In the structures first deduced for

tridymite¹⁴ and cristobalite,^{35, 46} the crystalline forms of silica which are stable at higher temperatures, the two bonds at each oxygen are assumed to be collinear. This may be the case at temperatures somewhat above room temperature, but, as later work has shown,² in cristobalite the Si-O-Si bond angles are somewhat less than 180°. This is probably also true of tridymite).

Because of the possibility, without much energy change, of different orientations of each Si-O bond relative to the other Si-O bond leading from the same oxygen atom, many different atomic arrangements satisfying the bond requirements just mentioned have nearly the same stability. The most stable of these, at room temperature, is that of quartz, but at much higher temperatures, many less regular structures must exist, in equilibrium with each other (See Fig. 1). A change from one of these structures to another involves (in most instances) the breaking of relatively strong Si-O bonds. The activation energy for this is large—so large that the rate must be negligibly slow at ordinary temperatures. Sudden cooling of the melt, through the temperature range within which this rate is not negligible, therefore “freezes-in” the irregular arrangements, producing silica glass.

Other Oxide Glasses

Other pure oxides which have yielded glasses on rapid cooling from the molten state include the following: B_2O_3 ,^{15, 30, 47} GeO_2 ,^{15, 30, 47} ZrO_2 ,¹⁰ P_2O_5 ,^{15, 30, 47} As_2O_3 ,^{15, 30, 47} As_2O_5 ,^{15, 47} Sb_2O_3 ,⁴⁷ and Bi_2O_3 .⁸⁴ Possibly P_2O_3 ,⁴⁷ V_2O_5 ,^{15, 30, 47} Sb_2O_5 ,⁴⁷ and SO_3 ,¹² should also be included in this list. In all of these substances one would expect, theoretically,—in both the crystalline and vitreous states—rather strong metal-oxygen electron-pair bonds. Except in ZrO_2 , one would expect two such bonds extending approximately at tetrahedral angles from each oxygen atom (or, in P_2O_5 , As_2O_5 , Sb_2O_5 , and V_2O_5 , from most of the oxygen atoms). The crystal structures of most of these compounds have been determined and have been found to agree with these theoretical expectations. According to both the theory and the crystal structure results, three or more of the oxygen atoms surrounding each atom of the more metallic element are bonded also to other “metal” atoms, except in the case of SO_3 . This permits a three-dimensional network structure, and such a structure doubtless exists in these glasses. The randomness of the atomic arrangements in the glasses results from the possibility of different relative orientations of the two bonds connecting each oxygen to other atoms and, in those instances in which all of the oxygens surrounding each “metal” atom are not also bonded to other atoms, from a randomness in the distribution of the bridging and nonbridging oxygens.

An amorphous, elastic form of sulfur trioxide can be produced¹² as a skin on the surface of a solution of SO_3 in SO_2 . This probably contains long, *kinked* chains, corresponding to the dot formula (pairs of dots representing valence electron-pairs)

These chains may perhaps have side chains; rings may also be present.

Silicate Glasses

In most silicates, both crystalline and vitreous, the Si-O bonds are much stronger than any others present. (B-O and perhaps Al-O bonds are comparable in strength. For simplicity we shall neglect these here.) In agreement with theoretical expectations, it has been found that in silicate *crystals* each silicon is tetrahedrally surrounded by four oxygens and that each oxygen is bonded to either one or two silicons. Such evidence as there is regarding the structure of silicate *glasses* favors the assumption that a similar state of affairs exists in these also.

The SiO_4 tetrahedra may be classified as types 0, 1, 2, 3, and 4, on the basis of the number of oxygens shared with other silicons. At least in crystals and glasses in which there are no other bonds comparable in strength with the Si-O bonds, it seems reasonable to assume that for greatest stability only types designated by adjacent numbers (0 and 1 or 1 and 2 or 2 and 3 or 3 and 4, but not 0 and 2 or 1 and 3, etc.) can exist together in a given sample. In other words, two SiO_4 tetrahedra of types 1 and 3 (having one and three oxygens shared), for example, would tend to react together in such a way as to produce two tetrahedra of type 2. The authors know of no contradictions to this generalization among silicate crystals. Among glasses we might expect some deviations, especially if the composition is such that nearly all of the tetrahedra are of a single type. For instance, a glass having nearly all of type 2 might well have some of type 1 and some of type 3. Nevertheless, some conclusions based on this generalization are of interest and may be considered to be approximately correct.

For this purpose, we make use of a quantity N_{Si} , defined as the ratio of the number of silicon atoms to the number of oxygen atoms in the glass (or crystal). It may be computed¹⁷ from the weight fractions (f_M) of the different oxide components (having formulas $M_m\text{O}_n$ and molecular weights W_M) by means of the relation

$$N_{\text{Si}} = \frac{f_{\text{Si}}/W_{\text{Si}}}{\sum n_M f_M / W_M} = \frac{f_{\text{Si}}/60.06}{\sum n_M f_M / W_M} \quad (14)$$

N_{Si} and s , the average number of oxygen atoms of each SiO_4 tetrahedron which are shared with other silicons, are related by the equation

$$s = 8 - \frac{2}{N_{\text{Si}}} \quad (15)$$

Table 1 gives both the values of s and of f_0, f_1, \dots, f_4 , the fractions of the SiO_4 tetrahedra which are of types 0, 1, . . . 4, respectively, for various compositions (N_{Si} values) and composition ranges, assuming the generalization stated above to be strictly correct.

Table 1. Hypothetical Dependence of Structures on Composition, for Silicate Glasses

| N_{Si} | s | f_0 | f_1 | f_2 | f_3 | f_4 | Diagrammatic Representation |

| .500 | 4 | 0 | 0 | 0 | 0 | 1 | Network, composed of ---+--- |

In the right-hand column, the silicate structures present are symbolized diagrammatically. The crosses represent SiO_4 tetrahedra: + denotes SiO_4^{-4} ions, having the "dot formula"

++ denotes $\text{Si}_2\text{O}_7^{-6}$ ions, having the dot formula

etc.

In the composition range $0.286 < N_{\text{Si}} < 0.333$, the average number of silicon atoms per chain is given by the equation

$$\bar{n}_{\text{Si}} = \frac{f_c N_{\text{Si}}}{1 - 3N_{\text{Si}}}, \quad (16)$$

where f_c is the fraction of the total number of silicon atoms which are in chains, rather than in rings.

Except for pure SiO_2 ($N_{\text{Si}} = 0.50$), each aggregation of silicon and oxygen atoms, joined together through Si-O bonds, is negatively charged, the magnitude of the charge being given by the formula $\text{Si}_x\text{O}_y^{4x-2y}$. This charge is balanced by positively charged ions, such as Na^+ , Ca^{++} , Al^{+++} , also present in the structure. The distribution of the positive ions, although of course important in determining the properties of the glass, will not be discussed at this time.

It must be emphasized that the distributions of silicon and oxygen atoms indicated in Table 1 are, at best, only approximate, limiting distributions. The energy change for the reaction between a type 1 tetrahedron and a type 3 tetrahedron to give two type 2 tetrahedra, for instance, is probably not large. At any temperature at which the rate of this reaction would not be negligible, it is probable that the equilibrium distribution would contain a considerable fraction of types 1 and 3 coexisting in the same sample. Glasses having $N_{\text{Si}} \leq 0.333$ would therefore be expected to have some branched chains and those having $N_{\text{Si}} \geq 0.333$ would be expected to have some chains with loose ends. The relative numbers of tetrahedra of the different types are certainly affected, also, by the kinds and numbers of other atoms or ions present, especially by those (B, Al) having the strongest attractions for the oxygens.

In spite of these limitations, it is felt by the authors that the dependence of structure on composition indicated in Table 1 is approximately correct and will prove useful in future discussions of the dependence of the properties of silicate glasses on their compositions. Considerations such as these have, in fact, already proved helpful in leading to reasonably satisfactory treatments of the dependence of the densities,^{17, 21} refractive indices,^{18, 21} and dispersions^{19, 21, 22} of silicate glasses on their compositions.

The conclusions regarding the structure of silicate glasses containing no atoms, other than silicon, which form strong electron-pair bonds to oxygen, are readily generalized, on the basis of similar assumptions, to other mixed oxide glasses—both those containing silicon, plus other elements such as boron, phosphorus, germanium, etc., and those containing no silicon.

For instance, Table 1 is applicable *in toto* to glasses containing as components only SiO_2 , GeO_2 , P_2O_5 , and As_2O_5 (in all of which each atom of the more metallic element is bonded to four oxygen atoms) and oxides of more electropositive elements, provided N_{Si} is replaced by $\sum_A N_M$, the summation being over the "Class A" elements:

Si, Ge, P^{V} , As^{V} . Boron can probably also be included among the Class A elements, provided $\sum_A N_M$ is less than one-half; otherwise some boron atoms will be bonded to only three oxygen atoms and the relationships are more complicated.

The assumption that types 1 and 3 (or 0 and 2 or 2 and 4, etc.) do not coexist is a more radical assumption if two or more Class A elements are present than if only one is present. Two or even three or four of the oxygens around many of the silicon atoms in a structure containing both silicon and phosphorus, for instance, may perhaps be shared, even though some of the PO_4 tetrahedra share none of their oxygens with other elements. If this sort of situation occurs, the generalization of Table 1, just described, is incorrect.

If the glass contains oxides of "Class B" elements, such as P^{III} , As^{III} and perhaps Sb^{III} (in which each of these atoms is bonded to only *three* oxygens), and oxides of more electropositive elements—but no oxides of Class A elements—Table 2 replaces Table 1. For simplicity, only those compositions corresponding to integral s values

Table 2. Hypothetical Dependence of Structure on Composition for Glasses Containing Oxides of Class B Elements

|--------------|-----|--|
| 0.333 | 0 | \perp |
| .400 | 1 | $\perp \perp$ |
| .500 | 2 | --- \perp --- (rings and/or infinite chains) |
| .667 | 3 | --- \perp --- (network) |

(or zero) are listed. The symbols \perp and $\perp \perp$, in the last column, represent (if M = phosphorus) PO_3^{-3} ,

and $\text{P}_2\text{O}_6^{-4}$,

respectively.

This table also is based on the assumption that types 0 and 2, 0 and 3, and 1 and 3, will not coexist; it may well be incorrect in many cases, especially if more than one kind of B atom is present.

If both Class A and Class B elements are present, Table 3 applies—again provided the corresponding assumption, regarding the mixing of different types, holds.

Further experimental and theoretical studies are required before one can proceed much further with the correlation of structure with composition, in glasses containing more than one type of element of Class A or Class B, or both.

If elements forming more than four strong bonds with oxygen are present, still further complications arise. These will not be considered here.

Table 3. Hypothetical Dependence of Structure on Composition for Glasses Containing Oxides of both Class A and Class B Elements

| Composition | s | Diagrammatic Representation |
|---|-----|--|
| $4\sum_A N_M + 3\sum_B N_M = 1$ | 0 | $+$, \perp |
| $\frac{7}{2}\sum_A N_M + \frac{5}{2}\sum_B N_M = 1$ | 1 | $++$, $\perp\perp$, $+\perp$ |
| $3\sum_A N_M + 2\sum_B N_M = 1$ | 2 | $\cdots+\cdots$, $\cdots\perp\cdots$ (rings and/or infinite chains) |
| $\frac{5}{2}\sum_A N_M + \frac{3}{2}\sum_B N_M = 1$ | 3 | $\cdots+\cdots$, $\cdots\perp\cdots$ (network) |
| $\frac{5}{2}\sum_A N_M + \frac{3}{2}\sum_B N_M = 1$ | 3-4 | $\cdots+\cdots$, $\cdots\perp\cdots$ (network) |

Glasses Containing Hydrogen Bridges

Glasses in which molecular (or ionic) units are held together by OHO hydrogen bridges will now be discussed. Most organic hydroxy compounds form vitreous masses of this sort. A typical example is glucose, which has the molecular formula

The possibilities of different orientations of the OHO bridges relative to the adjacent C—O bonds and of considerable variation in bond angles at (and within) these bridges, as well as other factors (in many instances), help to produce an amorphous rather than a crystalline structure. The forces tending to prevent rearrangement of a momentarily existing structure are much less than for silicate glasses; the substances are therefore fluid at much lower temperatures. This greatly simplifies the investigation of the variation of various properties with temperature, through the transition region between the liquid and the vitreous conditions.

Curves showing the variation with temperature of the specific heat, coefficient of expansion, and dielectric constant of glucose are shown in Fig. 9. It is evident that, although there is no actual discontinuity, as in the case of a crystal-liquid transition, rather large changes in these properties take place within a small temperature interval. As would be expected, the dielectric constant—the magnitude of which depends chiefly on the ability of the polar molecules and atomic groups to orient in the electric field within the time of a half-cycle—attains its maximum value only at temperatures at which the substance is quite fluid.

Two examples of vitreous substances composed (primarily, at least) of long chains, held together by means of OHO hydrogen bridges, may be mentioned. One is glacial phosphoric acid, one of the forms of metaphosphoric acid, HPO_3 . This substance, the authors believe, consists of long chains,

kinked in a more or less random manner and connected to each other by means of the hydrogens. Some closed rings may also be present.

FIGURE 9. Variation with temperature of the specific heat at constant pressure,³¹ coefficient of expansion,³¹ and dielectric constant³⁹ (at 92 and 2600 kilocycles per second) of glucose. Data by Parks and co-workers.

The other example is polyvinyl alcohol, which also consists chiefly of long chains,

On warming and stretching, the chains straighten out to a zigzag form and line up so that the axes are parallel, with different chains, in pairs, bonded together by hydrogen bridges, as shown in Fig. 10. In the unstretched (vitreous) state, each chain is kinked and connected by hydrogen bridges to many others, rather than to one only.

Organic Polymers

Polyvinyl alcohol is but one of many organic polymers containing long chains which are kinked in a random manner—provided they have not been extended and oriented by stretching of the material. Such substances are rigid solids if the activation energies for rearrangement of the atomic positions are large relative to kT . They are soft and non-rigid if these activation energies are roughly equal to, or smaller than, kT . They show rubberlike elasticity if (1) most of the atoms have considerable freedom of motion, being restricted only by small energy humps, yet (2) long-distance displacements are prevented by the existence of a three-dimensional

FIGURE 10. Projection of a pair of molecular chains in crystalline polyvinyl alcohol, according to Mooney.²⁹ The circles, in descending order of size, represent oxygen, carbon, and hydrogen. The dotted and solid circles distinguish between hydrogens on alternate sides of the chains.

network of strong bonds, capable of being broken only if large energy humps are passed over. Without such a network, these substances exhibit plastic flow, rather than long-range elasticity.

Many organic high polymers, although amorphous, are rigid, rather than elastic or plastic, at ordinary temperatures. Structural rearrangements are practically impossible because of the sizes of the energy humps which would have to be passed over. *Long-chain* polymers, as a rule, are *thermoplastic*—softening as the temperature rises, that is, as the thermal energy becomes great enough to pass over more and more of the energy humps. Many resins, however, contain three-dimensional networks of strong bonds, produced either by reactions together of small molecules—each becoming connected to more than two others, on the average—or by extensive crosslinking between already formed chain molecules. If these reactions, producing network formation, are induced by heat, the resin is said to be produced by a *thermo-setting* process. A three-dimensional network polymer is elastic or rigid, depending on the tightness with which the atoms in the network are held in fixed positions.

Low-molecular Organic Compounds without Hydrogen Bridges

Most pure organic substances composed of small molecules crystallize on slow cooling. This is an indication that a single definite distribution of molecular centers, with a single definite orientation for each molecule, gives somewhat greater stability than any more random arrangement. If, however, there are no localized intermolecular forces favoring a particular orientation of each molecule relative to its neighbors—or if such orienting forces are very weak—the substance is likely to produce a vitreous mass on cooling. Vitreous formation is especially likely if the molecules are irregular in shape and if there are two or more *intramolecular* distributions of atoms having practically the same energy and practically the same *intermolecular* attractions.

To illustrate these statements, it may be mentioned that many unsymmetrical *iso*-paraffins, unlike the *normal* compounds and the symmetrical *iso* compounds, form

vitreous masses, rather than crystals, on cooling from the liquid state.^{11, 16, 37} Glasses are also formed (at $\sim -160^\circ\text{C}$) by isoamyl and isobutyl bromides. The dielectric constants of these substances, as functions of temperature, frequency and previous treatment of the samples, have been the subject of an interesting study by Baker and Smyth.¹

The presence of more than one molecular species in the samples being cooled—especially if the different species are very similar as regards their intermolecular attractions—also favors the formation of a vitreous, non-crystalline material. Mixtures of isoparaffins, for example, usually become vitreous on solidification.³⁷ As all organic chemists know, the crystallization of organic compounds from impure melts can often be accomplished only with great difficulty, if at all.

Summary

In this chapter the difficulty of defining the vitreous state in a rigorous manner, the existence of many borderline cases, and the theoretical requirements which must be met if a substance is to be vitreous have been discussed. A start has been made toward the development of a quantitative treatment of the subject. Certain typical classes of vitreous substances have been treated in some detail, with especial regard to the relationships between their structures and vitreous properties.

Some Irreversible Effects of High Mechanical Stress *

P. W. BRIDGMAN

Research Laboratory of Physics, Harvard University

Some more or less arbitrary selection of the irreversible effects to be considered is necessary because of the vastness of the subject if all irreversible phenomena are admitted. Thus every case of rupture, or of plastic flow in a solid, or of flow of a viscous liquid is properly an example of an irreversible effect produced by mechanical stress. The overwhelming majority of the processes of daily life, which are side-stepped by thermodynamics on the plea that they are "irreversible," are of this kind. It is possible to distinguish various possible meanings for "irreversible." I shall use it with the connotation of thermodynamics as implying a dissipation of energy or increase of entropy, and rule out such purely mechanical cases of irreversibility as the winding of a watch with a ratchet. All that I can attempt in this enormous field is to select some of the more interesting and unusual cases, and the selection will usually be from instances which have occurred within my own experience in the laboratory. The "high" mechanical stress of the title is also in general fixed by my own laboratory experience, which means stresses of the order of thousands of kilograms per square centimeter.

Within this field it is possible to set up a formal scheme for systematic treatment. The mechanical stress may be distinguished as being either a pure hydrostatic pressure, or something more complicated, with a shearing component. The sorts of effect produced by the stress may be distinguished as consisting of: (1) rearrangements or distortions of the initial atomic arrangement which occur without change of type of space lattice, as in recrystallizations or various accommodation effects, or (2) a rearrangement of the lattice into a new type, thus constituting a change of phase, or finally (3) chemical changes, including both decompositions and syntheses. The combination of the two different stress factors with the three sorts of change gives a formal classification of six kinds of irreversible change to be considered.

EFFECTS OF HYDROSTATIC PRESSURE

Effects Not Involving Phase Change or Chemical Reaction

Under this heading come the ordinary mechanical effects. Every body, so far as recorded human experience goes, is completely elastic if the stress within it is a pure hydrostatic pressure; rupture or permanent change of dimensions never occurs. No one knows whether hydrostatic pressures of very much greater intensity than are available under terrestrial conditions, such as the pressures in the interiors of the stars, would squeeze matter permanently to the density of the companion of Sirius or not. Although cases have been observed in terrestrial laboratories of permanent increases of density under hydrostatic pressure, cavities have always been initially

* Many physico-chemical effects involve the close approach of particulate units. It is therefore of great interest to consider some of the results of high pressures, which have both theoretical and technological aspects. J. A.

present. Of course, if such cavities are present, the stress in the immediately neighboring walls is not a hydrostatic pressure, even if the whole body is immersed in a fluid under pressure. Our generalization thus stands even in such apparently exceptional cases. There are other situations in which the stress within the interior of a solid body is not a hydrostatic pressure even when the body as a whole is immersed in a fluid under pressure. The compressibility of non-cubic crystals is in general different in different directions, so that the geometrical shape of such a crystal is altered when the crystal is placed in a fluid under hydrostatic pressure. It follows that the stress in a haphazard aggregate of non-cubic crystals is not hydrostatic when immersed in a fluid carrying hydrostatic pressure, but is a complicated function of the relative orientation of the different crystal grains. If the hydrostatic pressure in the fluid is not too high, the adaptations demanded in the neighboring grains will be within the elastic limit, and the effects are reversible. When pressure rises too high, however, local elastic limits are exceeded, and the effect becomes irreversible. Any permanent change of dimensions produced in this way is, under the laboratory conditions of my own experience, in many cases too small to be important, although detectable, but there are other effects which may be larger. In particular, the electrical resistance of a polycrystalline wire of non-cubic crystals is often permanently altered after an application of hydrostatic pressure. After a number of applications of pressure, such a wire settles down to a steady state with no further alteration of zero resistance as long as the original pressure range is not exceeded. The more complex the structure, the more complex and unusual the effects. Such effects are particularly likely to be found in rocks or minerals. "Pipestone," or catlinite, is a very fine-grained and perfectly homogeneous-appearing mineral to the eye. But if its linear compressibility is measured,¹ it will be found that the change of length is not a linear or even single-valued function of pressure, but describes a loop, closed at both ends, which can be repeated indefinitely. Furthermore, this loop is not like the ordinary hysteresis loop, in which the strain lags behind the pressure: the strain is in advance—a highly paradoxical effect.

Most rocks are either initially porous, or else are made porous by hydrostatic pressure because of the differential compressibility of the grains. Dr. Birch² has encountered many examples of this sort of irreversibility in his measurements on rocks. In general, it is necessary to specify whether the measurements are made with the rock directly immersed in the pressure fluid, or "jacketed" to prevent entrance of the liquid into the pores.

If the material is not initially perfectly free from internal strain, in some cases the application of hydrostatic pressure will produce irreversible changes of geometrical form. This effect is particularly prominent in glass, and it is not unusual for a badly annealed glass vessel to be broken by the application of hydrostatic pressure. It is almost impossible to get accurate values for compressions at pressures of the order of several thousand kilograms in glass piezometers, because of the hysteresis of the glass. One case of disorganization of internal structure by pure hydrostatic pressure has been reported. Meyer, Hopf, and Mark³ report that starch which has been exposed to 20,000 atmospheres gives a disordered x-ray pattern; it is natural to suspect the presence of a shearing component in the stress.

Effects Involving Phase Changes

We may distinguish less and more drastic effects produced by pressure. In the less drastic sort of change, the new phase which is induced to appear by the action of pressure is the thermodynamically stable phase, which might have appeared reversibly at a slightly different pressure or temperature; the action of pressure in inducing the appearance of the phase is simply that of an agitator, suppressing or diminishing the effect of internal friction. In the more drastic sort of change, pressure causes a new phase to appear, which is not formed reversibly from the initial

phase under any known conditions. The less drastic sort is by far the most common. Practically all liquids subcool to a certain extent before freezing, and practically all transitions between solids have to be carried an appreciable distance beyond the point of thermodynamic equilibrium before the reaction will start. Any phase change which thus runs displaced from the point of thermodynamic equilibrium runs irreversibly. This very common phenomenon may, however, be manifested in various ways.

To visualize the possibilities, consider the phase diagram of a substance, in which temperature and hydrostatic pressure are coördinates, and the regions of thermodynamic stability of the different phases are separated by the various transition lines on which the adjoining phases are in thermodynamic equilibrium. Consider now a phase initially at some temperature and pressure within its region of stability, and then carry it, by variation of temperature or pressure, across one of the bounding transition lines into the region of thermodynamic stability of another phase. The reaction from the phase which has now become unstable to the new phase involves two different sorts of phenomena: a nucleus of the new phase must be formed, and after the nucleus has been formed, the surface of separation between the two phases advances by a molecular rearrangement at the surface. Since one can arrive at a given point in the diagram either by a variation of pressure along the isothermal passing through the point or by a variation of temperature along the isobar passing through the point, it is arbitrary whether one chooses to describe the irreversible transition which is occurring at the point as brought about by a change of temperature or a change of pressure (or both).

Nucleus formation is the necessary precursor of the transition. The rapidity with which new nuclei are formed is a function of the coördinates of the point in the phase diagram. At first, as the point recedes from the transition line, the speed of formation of new nuclei will in general increase. A precise study of the variation of speed of nucleus formation as a function of the coördinates all over the pressure temperature-pressure plane is evidently necessary for a full understanding of the possibilities, but only very partial studies have been made. Tammann,⁴ fifty years ago, studied the speed at atmospheric pressure as temperature is depressed. His important result was that in many cases the speed of nucleus formation passes through a maximum as temperature is lowered below the point of thermodynamic equilibrium, and beyond the maximum may drop to practically zero with further drop of temperature. This indicates what we are to expect in the full temperature-pressure field. As we travel away from the line of thermodynamic equilibrium, we are to expect that in general the speed of nucleus formation will at first increase, pass through a maximum, and then decrease. Incidentally, there is no reason to think that the speed becomes zero on the line of thermodynamic equilibrium, but the possibility should be recognized that there is a finite speed of formation of the nucleus of phase *B* within the region of thermodynamic stability of the phase *A*. As long as the rate of growth of the surface of separation of phase *B* into phase *A* is negative or zero in this region, there is no trouble. One of the reasons why we should expect a fall in speed of nucleus formation with increasing pressure is obviously the increased viscosity produced by increasing pressure; this for certain organic substances⁵ may be as high as 10^7 fold for a pressure increase of 10,000 kg/cm². This point of view makes it doubtful whether a maximum is to be expected if the displacement from the transition line is in the direction of decreasing pressure; so far as I know the question has never been investigated by direct experimental attack, and there is no indirect evidence in all my experience that such a maximum ever occurs with decreasing pressure. There are, however, effects which become understandable if there is a maximum with increasing pressure. For example, the reversible melting pressure of ethyl acetate at room temperature is about 12,000 kg/cm². The solid is very reluctant to appear, however, and pressure may be

carried from 12,000 to 50,000 without freezing.⁶ But on release of pressure, when the melting pressure is approached within approximately 10,000 kg/cm², nuclei of the solid are formed and the liquid freezes irreversibly. This freezing has a most paradoxical appearance, for it is a phase change with decreasing volume brought about by a decrease of pressure. Such a transition is thermodynamically impossible if it is reversible. Another, somewhat similar, example⁶ is afforded by CBr₄, in which a transition runs against the direction possible for thermodynamically reversible transitions when the region of appreciable velocity of nucleus formation is entered from above. In the latter case, the phenomena have additional complications, for which the original paper must be consulted.

The speed of advance of the surface of one phase into the other is the second factor determining how a transition actually runs. For common substances this speed is zero at the thermodynamic equilibrium line, and increases at distances from the line. Whether it also passes through a maximum as pressure increases at constant temperature has not been established by direct means, but the presumption is that it does. The increase of viscosity brought about by pressure would lead one to expect it, and I have recently found⁶ on measuring melting curves over a pressure range reaching up to 40,000 kg/cm² that the tendency is for freezing to become much more sluggish at the high pressure end of the curve. For instance, the solid and liquid forms of methyl cyclohexane were maintained in contact for a couple of hours at pressures varying from 12,000 to 50,000 in the region of stability of the solid, during which less than one-tenth of a volume of 0.2 cm³ froze. Under normal conditions the freezing is not notably sluggish.

There are substances, moreover, for which the speed of advance of the phase vanishes, at least to a different order of small quantities, within a finite region on both sides of the thermodynamic transition line, so that within this region the two phases may exist indefinitely in contact, in spite of the fact that thermodynamically they are out of equilibrium. A transition between two such phases must always run irreversibly. Many examples of such have been found.⁷

In view of all these general considerations, one would expect to find cases of substances which at atmospheric pressure are not far from a line of thermodynamic transition to another phase, but which can be forced to assume this other phase by the exercise of sufficient pressure to bring it into the region of finite velocity of nucleus formation, and which when then brought back to atmospheric pressure retain the new phase because the reverse transition velocity is too low. Such cases do exist, but they are not as common as perhaps might be expected. Thus selenium exists in both a crystalline form and a glassy modification. By application of 50,000 kg/cm² to the glassy modification some of it is permanently and irreversibly transformed, presumably to a crystalline form.⁸ As another example, complicated and not yet elucidated internal changes are produced in arsenic⁹ by hydrostatic pressures of the order of 10,000 kg/cm².

If one avails oneself of full coöperation between changes of temperature and of pressure one may find many examples of the realization of phases under atmospheric conditions which are normally unstable. Thus one may first raise the temperature to a region of appreciable transition velocity; then raise pressure until the domain of stability of a new phase has been entered and the new phase appears; then lower temperature under pressure so as to maintain the new phase; and then remove pressure at room temperature, where the transition velocity has become sensibly zero, so that the unstable phase is maintained. Any substance which has phases with finite reaction velocities at high temperatures and zero velocities at low temperatures should show this phenomenon; a number of examples will be found in my papers. One of the most spectacular is afforded by ice. It was first shown by Tammann¹⁰ that the unstable ices II and III could be realized at atmospheric pressure at liquid air temperatures. The ices were formed by the action of pressure

at temperatures of perhaps -40° where the reaction velocity is considerable; and then the apparatus was cooled in liquid air, pressure released, and the apparatus opened. Dr. McFarlan¹¹ has made x-ray determinations of the structure of these ices by utilizing this effect, and has found that they are apparently indefinitely permanent at atmospheric pressure at liquid air temperature.

If the system is not chemically homogeneous, irreversible effects are easily produced by the application of hydrostatic pressure. Thus when an impure liquid is forced to freeze by the application of hydrostatic pressure, the impurities may separate on freezing and segregate in the bottom of the receptacle. When pressure is released, because of the finite time of solution and the time required for equilibrium to be set up by the action of convection currents, the system will not retrace its original configuration, so that the phenomenon is irreversible. Kerosene is such a substance.

Recently, increasing attention has been given to transitions other than the simple transitions of the "first kind" characterized by sharp discontinuities in volume and energy content. For example, the new types of transition occur in conjunction with the anomalies of the specific heat and thermal expansion of some substances at low temperatures. These transitions do not run with sharp discontinuities, and show hysteresis between increasing and decreasing temperature. Such hysteresis is always evidence of irreversibility. Since the transition temperature is in general a function of pressure, hysteresis loops should also be producible for such substances by a change of pressure at constant temperature. I have found¹² several examples of such loops at room temperature among the alloys; these loops are obtained when length is measured as a function of pressure. An especially large effect of this kind is shown by a non-metallic substance,¹³ Ag_2O . Other physical properties similarly would be expected to show hysteresis, electrical resistance, in particular. Wilson¹⁴ has found such electrical effects for a number of alloys which are known from other considerations to be capable of the order-disorder transition.

Hydrostatic pressure is known to affect the speed of certain irreversible reactions. Thus van Wert¹⁵ found that the speed of segregation of the insoluble component of several age-hardening alloys is lowered by the application of pressure.

In all the examples hitherto considered, the phase which has been induced to appear irreversibly by the action of pressure is one which somewhere has a region of thermodynamic stability, so that the reaction may be made to run reversibly under proper conditions. But there are other phase changes produced by pressure which are not known ever to occur under reversible conditions. These are the more drastic reactions already referred to. Not many examples of these are as yet known. An example is HgS . This is known to the chemist in two forms: black and red. The black form is unstable and may be transformed into the red by an increase of temperature at atmospheric pressure. In nature the red form is common, but there is mention of a natural black form in textbooks of mineralogy. Professor Palache, however, states that he has never found any of these supposedly black forms in nature which did not turn out on examination to be really red; he believes that the black form never appears in nature. This is consistent with the observation¹⁶ that the unstable black form made artificially in the laboratory is irreversibly transformed into the red by the application of hydrostatic pressure at room temperature.

Another example is black phosphorus. If ordinary yellow phosphorus is heated to temperatures above 200° and subjected to pressures of more than $12,000 \text{ kg/cm}^2$, it is irreversibly transformed¹⁷ into a black form with large decrease of volume and drastic change in its physical properties; the new form superficially resembles graphite. The phenomena have recently been examined in much detail by Jacobs,¹⁸ who finds that there are at least two forms of black phosphorus and that the relations are highly complex. I have found that black phosphorus may also be formed from yellow at room temperature¹⁹ by pressures above $35,000 \text{ kg/cm}^2$.

Recently it has been found²⁰ that when CS_2 is subjected to pressures in excess of 40,000 kg/cm² and temperatures above 175° it is irreversibly and permanently transformed to a black solid, which must be a new form of CS_2 . It cannot be a mechanical mixture of the constituent carbon and sulfur, because the density is 4 per cent greater than that of such a mixture, and it does not melt or soften at the melting point of sulfur, but decomposes slowly when the temperature is raised to the neighborhood of 200°.

There seems to be no theoretical method at present of anticipating the possibility of such substances as black phosphorus or solid carbon disulfide; if these had not been found experimentally after exposure to unusual conditions their existence would never have been suspected. It is fascinating to speculate whether it may not be possible that many other of the substances of ordinary experience can be pushed over a hill of potential into a new, permanent, and totally different form, if only sufficient pressure is applied.

Chemical Changes Produced by Hydrostatic Pressure

Among the complicated compounds of biology a comparatively large number are known which may be changed permanently by the application of hydrostatic pressure. Early in the century it was found at the West Virginia Agricultural Experiment Station²¹ that microorganisms of various kinds are killed by the application of hydrostatic pressures of 5,000 or 6,000 kg/cm², and the application of such pressures was proposed as a commercial method for the sterilization of milk and canned products. Similar experiments were made later in my laboratory by Dr. Bovie and Stuart Ballantine, but were never published. I had previously found²² that egg white and the proteins of meat are coagulated by pressures of the same order. This coagulation gives an explanation of the killing of microorganisms. Somewhat later Dr. Alice R. Davis made unpublished experiments in my laboratory on the coagulation of blood. Dr. Davies²³ published a thesis in the Department of Biology of Harvard University on experiments with my apparatus in which he established that the germination of certain seeds is much facilitated by an exposure to pressure. The optimum pressure was around 2,000 kg/cm²; the seeds were killed by pressures much higher. This effect has received no sufficient explanation. It is not grossly mechanical, because no cracks can be discovered under the microscope in the coatings of the seeds. Germination is known to require some preliminary physicochemical change within the seed after ripening on the plant; this change may possibly be hastened by pressure, analogous to coagulation. I have found in unpublished experiments that the effect is not the same on all species of plants. Recently Dow²⁴ and his pupils have made similar experiments. Going a step beyond microorganisms, it has been found by Basset²⁵ and his collaborators that ferments, enzymes, and viruses may be killed by high pressures; the pressures required to kill these substances may rise as high as 15,000 or 20,000 kg/cm².

Among less complex organic compounds Conant and collaborators²⁶ have found a number of examples of polymerization. For example, isoprene is polymerized to rubber. This is probably not a straight pressure effect because of the smaller volume of the polymer. This might at first appear to be the natural explanation, because the volume of isoprene, for example, is under normal conditions materially larger than that of its polymer. The speed of the polymerization increases very rapidly with increasing pressure, however, whereas the volumes of the two substances become more nearly equal with increasing pressure. The highest rate of polymerization of all was found at 20,000 kg/cm², and at this pressure there is practically no change of volume when the reaction runs. Conant came to the conclusion that the largest part of the effect is the catalytic action of slight impurities, contact between catalyst and isoprene being furthered by the pressure.

Among the simpler inorganic compounds the examples of chemical changes

produced by pressure are less numerous. HgTe appears to be a case of a true pressure effect.²⁷ This compound is formed from the elements with considerable increase of volume, unlike the vast majority of compounds, so that decomposition to the elements would be facilitated by hydrostatic pressure. This does in fact slowly occur at pressures higher than 10,000 kg/cm². Another effect, not uncommon, is for the water of crystallization to be squeezed out of a salt by hydrostatic pressure.²⁸ Although this process may be thermodynamically reversible on a microscopic scale, as it actually occurs it is irreversible because of the mechanical segregation of the constituents. Similarly, certain double salts have been decomposed by pressures of 10,000 kg/cm² or more; (NH₄)₂KPO₄ is an example.²⁹ I have observed one example of an explosion produced by pure hydrostatic pressure.³⁰ A mixture of kerosene and NaClO₃ may be made to explode at room temperature by the application of somewhat over 2,000 kg/cm². It is curious that the chemically less stable KClO₃ cannot be made to explode by similar treatment.

There is an effect of pressure which is the reverse of decomposition. Many organic compounds decompose when temperature is raised. In a number of cases I have found that this decomposition is inhibited by the action of hydrostatic pressure. Thus CBr₄ has been heated to 175° without decomposition under pressure,³¹ and urea to 200° at pressures of 10,000 kg/cm² or more.³² There may be interesting possibilities here of bringing organic substances into reaction at temperatures where normally reaction would be impossible because of decomposition.

EFFECTS OF STRESS WITH A COMPONENT OF SHEAR

Effects Involving neither Phase Change nor Chemical Change

As already suggested, all cases of rupture properly belong here. There is space to mention only two rather unusual sorts of rupture which occur only at high stresses. Under normal conditions any piece of glass is covered with a surface layer of water many molecules deep so tightly sorbed as to be virtually in solution. If the glass is immersed in water and exposed to a pressure of several thousand kilograms, the water is driven into solution in the glass to a greater depth. When pressure is released the glass may be ruptured because of mechanical strains set up by the water trying to come out of solution.* Rupture may be avoided if pressure is released with extreme slowness. This effect was established by Poulter.³³

The opinion has often been expressed that any two bodies ought to adhere if they are only pressed together hard enough. The idea, of course, is that if they are pushed so close together that the parts are brought within the range of molecular forces, there is nothing to distinguish the body from one initially in one piece, so that welding must occur. Ordinarily these simple considerations are complicated by the fact that any body in the air is covered by a film of adsorbed air molecules, so that molecular contact cannot be forced, and the expected welding normally does not take place. If, however, a body is fractured deep in its interior, so that an adsorbed gas layer never has a chance to form, and if the body is under a high mean hydrostatic pressure so as to push the fractured surfaces immediately into contact again, it is to be expected that any fracture will immediately heal itself.

I have arranged conditions of this sort in some recent experiments.³⁴ Small quantities of various materials have been subjected to mean pressures of 50,000 kg/cm², and while under this pressure have been subjected in addition to shearing stresses of sufficient magnitude to produce plastic flow. Many bodies will not permit indefinite plastic flow under such conditions, but when flow has proceeded to a critical extent, the substance breaks with a snap, and the shearing stress drops to

* According to Zsigmondy, the explosive eruption of Mt. Pelée (Martinique) involved a pressure-solution of water in volcanic rock or glass, and its fine pulverization and dispersion when the pressure was suddenly released. Bentonites seem to have been laid down similarly. J. A.

zero. Because of the prevailing hydrostatic pressure, the material immediately self-welds, and the whole process may be repeated indefinitely. A simple description of the phenomenon is that the body "lets go to get a fresh hold." It must be that fractures occur under such conditions deep in the interior of the earth; the application to geophysics and in particular to the explanation of deep-seated earthquakes need not be elaborated.

Not only does self-welding occur under such conditions, but if one material is sheared across the surface of another under sufficient normal stress and for a sufficient distance to rub off any initially adhering film of gas, welding may be expected to occur. In my shearing experiments many examples of such welding have been found. Thus borax glass may be welded in the cold to steel just as tightly as if it had been fused.

An interesting example of the efficacy of the adsorbed surface film is afforded by the behavior of mercury and iron. Normally mercury does not wet iron, nor can it be made to amalgamate with it. If, however, a piece of iron is fractured under the surface of mercury, thus exposing a perfectly clean surface, the iron is completely wet and amalgamated. Amalgamation of iron may be produced by pressure. A hollow cylinder filled with mercury will support an internal pressure of only a few thousand atmospheres;³⁵ at higher pressures the mercury is driven by the pressure into the expanded pores of the iron, where it produces amalgamation because the iron is clean. Since the amalgamated region is mechanically much weaker than the untouched iron, the system is mechanically unstable, the amalgamated region rapidly eats its way through, and the cylinder bursts.

Recrystallization is a well known phenomenon brought about by shearing stress. The classic experiments of Carpenter and Elam³⁶ come to mind in which large single crystals of aluminum are grown in sheets that have been stretched beyond the elastic limit and then suitably annealed so that recrystallization takes place. A converse effect is the observation by Kapitza³⁷ that the success of producing single crystals of bismuth by solidification from the melt is very sensitive to slight mechanical stress. During the recrystallization that occurs when a polymorphic transition is brought about by a change of pressure, the growth of the new form may take place in a strongly preferred direction,³⁸ and may exert non-hydrostatic stresses sufficient to rupture heavy steel containers.

All sorts of minor rearrangements may be brought about by shearing stresses, ranging up to almost complete destruction of the lattice and amorphization, as when the surface film of a metal is heavily flowed by polishing. Elastic after-effects, and phenomena of creep, accommodation, and hysteresis are to be found here. Under conditions of high stress such effects may sometimes assume paradoxical forms. Thus I have found³⁹ that if a heavy-walled hollow cylinder is strongly collapsed by a high external pressure so that the internal bore is reduced to a fraction of its initial value while still retaining its circular figure, and if the external pressure is then released, such a complicated state of strain may be produced in the walls that the initial effect of a reapplication of pressure to the outside is to *increase* the internal bore. Or, it is not unusual for such heavily collapsed cylinders to fracture in extension across axial planes on *release* of external pressure.⁴⁰ Heavy glass cylinders exposed to external pressure may at first show no obvious effect on release of pressure, but that nevertheless some flow has been produced is shown by the fact that they may spontaneously fracture on standing for some hours.

It at first appears paradoxical that the density of metals is usually decreased by the heavy stresses that produce plastic flow; the reason is that the regular space lattice of the virgin material is a closer-packed arrangement than the more amorphous aggregate to which the metal is reduced by flow.

If plastic flow is sufficiently prolonged, a steady state must eventually be reached. This steady state probably consists of a highly distorted lattice, parts of which may

be so highly distorted as to be essentially a glass. A. B. Greninger at the Harvard Metallurgical Laboratory has made many x-ray analyses of metals sheared under high pressure; the structure in nearly every case is very much broken up. The lines are broadened, and the size of the elementary grains is very much reduced. One extreme case has been recently found,⁴¹ sulfur, where there are no x-ray lines at all in the final product; but in general complete reduction to a glass does not occur. Microscopic examination by Larsen⁴² seems to establish, however, that a portion of the distorted material at least sometimes is in the condition of a true glass. There is a converse effect; if a true glass is sheared at high stresses some lattice structure is produced. Thus when quartz glass is sheared, faint x-ray lines of crystalline quartz appear.

Geology is full of examples of recrystallization in orientations definitely related to the direction of flow. This effect has been studied by Sander.⁴³ It has been found possible to imitate a number of these orientation effects in the laboratory.⁴²

Phase Changes Accompanying Shearing Stress

The effect of non-hydrostatic stresses on phase-changes has been very little investigated. Formally, the possibility must be recognized that a substance may exist in thermodynamic stability under high enough shearing stress in a form which may never be stable under any hydrostatic pressure whatever. The conditions of reversible transition under such conditions should be capable of formulation, but so far as I am aware no attempt has ever been made. Doubtless the reason is the absence of experimental evidence for the existence of such phenomena. There is one case which I have observed,⁴⁴ however, which may belong in this category; in my experiments with lithium under shearing stress at pressures of 50,000 kg/cm², I found a sharp break in the curve of a sort which in all other cases corresponds to a polymorphic transition which can be realized at some hydrostatic pressure. In the case of lithium, however, there is no such transition under any known hydrostatic pressure, even when pressure is extended to 100,000 kg/cm², as I have done recently.⁴⁵

Shearing stress does exert a very great effect, however, on many ordinary polymorphic transitions. In general, the effect is that of an agitator or reducer of internal friction, so that the transition will run at pressures closer to the line of thermodynamic equilibrium, or at temperatures so low that ordinarily it would not run at all. Transitions may thus be made to run at room temperature by the exercise of a shearing force great enough to produce plastic flow, which under pure hydrostatic conditions have ceased to run perceptibly at temperatures 100° or perhaps 150° higher. Or, a transition may be made to occur under shearing stress that is not known to occur at all without it; thus *violet* phosphorus may be converted to black by high shearing stresses at room temperature combined with a high mean hydrostatic pressure.⁴⁶ This transition is, of course, irreversible, as are all the changes induced only by shearing stress, with the possible exception of lithium.

Wurtzite is completely converted to sphalerite by shearing under pressure.⁴⁷ Chalcocite is similarly changed to the ordinary cubic modification of Cu₂S. Complicated changes are produced among the various modifications of SiO₂, with evidence for a new crystalline form under some conditions.⁴²

There are cases in which phase changes originally ascribed to hydrostatic pressure turn out to be actually produced by shearing stress. Thus Jeffries⁴⁸ has shown that many instances of permanent alteration of density ascribed by Kahlbaum to high hydrostatic pressure are to be explained by the plastic flow which was produced in the metal by the congealing of the oil with which pressure was transmitted.

Chemical Changes Brought About by Shearing Stress

Perhaps the first attempt at a systematic investigation of this subject was made in 1893 by Carey Lea,⁴⁹ who found many examples of chemical reactions under the

shearing stresses produced by vigorous rubbing of a pestle in a mortar. It is obviously difficult under such conditions to make any good estimate of the intensity of the stresses involved. This investigation of Lea attracted little attention, and apparently has been forgotten. I did not discover it myself until making a literature search in connection with my shearing experiments.³⁴ During these experiments I have observed many cases of irreversible chemical change produced by shearing stress; in fact, irreversible permanent changes are the only ones that can be established, there being no way of observing the product during the application of stress. Except for a specification of the magnitude of the stresses involved, however, these experiments of mine have been mostly qualitative in character. The reason is that the quantities of transformed material are so minute that in most cases an analysis of the product is not feasible. The reasons why the quantities are so minute are first, that the original quantities have to be small, and secondly that the altered material is in most cases confined to a thin surface layer, since the reaction is usually self-limiting. This self-limiting quality is explained by the fact that when a thin surface film of the new product is once formed, stress is thereby prevented from building up to the transformation stress in the rest of the original material. The fact of some sort of transformation can be established in many cases by alterations in the surface color. My detailed paper must be consulted for many special cases. Thus a brown discoloration frequently appears on shearing the compounds of cesium. There are, however, some cases in which the transformation occurs throughout the entire mass, or at any rate through a mass large enough to be susceptible to x-ray analysis. There are numerous examples of reduction of a salt to one of different valence, or of complete decomposition to the metal. Thus SnO_2 is reduced to SnO ; Bi_2O_3 is reduced to metallic bismuth. Decomposition to the pure metal occurs especially among the salts of bismuth, mercury, and lead. Syntheses may be effected; thus copper and sulfur sheared together are converted to CuS . The thermite reaction is initiated by shearing under pressure, with explosive effects.

Transformations among the organic compounds are not as frequent as among the inorganic, perhaps because of a greater effect of increased viscosity and molecular interlocking. Anthracene,⁵⁰ however, affords an example of complete and irreversible conversion to some black substance.

In an address presented to the Congrès Internationale de Physique in Paris, 1900, Walthère Spring mentions the work of Carey Lea and much other early work (see "Oeuvres Completes de Walthère Spring," pp. 1746-1814, Brussels, 1923). Incidentally, in another paper (p. 1850) Spring points out that he had used the ultramicroscopic method prior to Siedentopf and Zsigmondy, and had sent one of them a reprint of his paper on request. Spring did much work showing that at high pressures chemical and physical unions take place.

The following item of interest appears in Technical Manual TM 9-2900 of the War Department, and is here given by permission (p. 118): "When loaded into commercial detonators, mercury fulminate is usually compressed at pressures of about 3,000 pounds per square inch. In this condition its explosive properties are not appreciably different from those of loosely pressed material. At greater densities obtained by higher pressures, there is a gradual reduction in sensitivity, until at such extreme pressures as 25,000 to 30,000 pounds per square inch fulminate entirely loses its property of detonating when ignited and will only burn. In this condition it is referred to as 'dead pressed.' If, however, such highly pressed fulminate is initiated by loose fulminate or other initial detonating agent, it will detonate at even higher rates than are obtainable at low densities." [Note added by the editor with the approval of the author.]

Sonic and Ultrasonic Waves in Colloid Chemistry

KARL SOLLNER

University of Minnesota, Minneapolis, Minnesota

Introduction

High-frequency inaudible sound waves, "ultrasonics," of great intensity are able to produce a great diversity of phenomena pertaining to the realm of colloid chemistry, as first shown in 1927 by R. W. Wood and A. L. Loomis.²⁵⁶ Later it was found that substantially the same phenomena may be likewise obtained with low-frequency sound waves, provided their intensity is sufficiently high.

It must be emphasized that there is no fundamental physical difference between ultrasonics and audible sound. The distinction is based on a virtually accidental physiological difference—the ability of the human ear to respond to sound frequencies between about 16 cycles per second and about 15,000 to 20,000 cycles per second. Higher and lower frequencies are inaudible. Sound frequencies above the audible range are commonly referred to as "ultrasonics" or "suprasonics."

Sound waves of high intensity may bring about all kinds of phenomena of dis-

persion, such as peptization, the mutual emulsification of two bulk liquid phases, the disintegration of certain solids, the depolymerization of high-molecular substances, the formation of fogs, etc. On the other hand they may also cause accumulation, aggregation and coagulation in liquid as well as in gaseous systems, and the orientation of anisometric particles, etc.

High-intensity sound waves may cause some additional phenomena of interest to the colloid chemist; they favor the formation of new phases, *i.e.*, start and accelerate the crystallization from many supersaturated solutions and affect the crystalline structure of metals and alloys when applied to the melts during the period of cooling and crystallization.

Though there are no fundamental physical differences between sound waves of low, medium and high frequencies, great differences exist in the ease with which high intensities may be produced and the ease with which the sound energy may be transferred to the system under investigation. For most colloid work sound intensities are used which are much greater than those to which we are accustomed. For example, to produce emulsification an intensity of 10 watt/cm² is necessary, compared to the 10⁻⁹ watt/cm² of a comfortably tuned radio.

Originally all the work in colloids was done with ultrasonics of several hundred thousand cycles per second; lately frequencies down into the audible range have been more and more used.

The fact that the wave length decreases as the frequency increases makes itself felt in all experimental work; with higher frequencies the experimental system may easily be made many times larger than the wave length. Another important fact is that the absorption of high-frequency waves is much stronger than that of lower frequencies. (See p. 355). At very high frequencies the energy losses due to absorption become excessive. This seems to be one of the reasons why hardly any colloid-chemical work has been done with frequencies of more than a million cycles per second. On the side of the lower frequencies another difficulty arises. The amplitudes necessary to transmit a given quantity of energy at low frequency are much greater than those at higher frequencies. At medium and lower audible sound frequencies the necessary amplitudes are actually so large that the mechanical strength of the vibrators is the factor limiting the sound transmission; unless the amplitudes stay below a certain limit, the vibrators are destroyed.

To obtain an idea of the wave length, λ , of sound waves of different frequencies, n , we must remember the simple equation $V = n\lambda$, V being the sound velocity. Table 1 is calculated on the basis of this equation. Readers interested in accurate information on this and other points concerning the pure physics of ultrasonics must be referred to the literature, *e.g.*, the monograph of Bergmann,^{6, 7} and particularly to the excellent book of Hiedemann.¹⁰⁸

Table 1. Wave Length at Different Sound Frequencies in Air, Liquids and Solids

| Frequency n (cycles per second) | Wave Length (λ) | | |
|--------------------------------------|----------------------------------|---|--|
| | Air ($V = 330\text{m/sec}$) | Average Liquid ($V = 1200\text{ m/sec}$) | Average Solid ($V = 4000\text{ m/sec}$) |
| 16 (audible) | 20.6 m | 75 m | 250 m |
| 435 (") | 76.0 cm | 2.75 m | 9.2 m |
| 15,000 (") | 2.2 cm | 8.0 cm | 26.6 cm |
| 25,000 (ultrasonic) | 1.3 cm | 4.3 cm | 16.0 cm |
| 200,000 (") | 1.6 mm | 6.0 mm | 2.0 cm |
| 1,000,000 (") | 0.3 mm | 1.2 mm | 4 mm |

Sonic and Ultrasonic Generators

The literature on sound generators useful for colloid work has never been discussed critically, or even collected in one place. However, the success of further

work in this field will necessarily depend upon the correct choice of experimental equipment.

It is beyond the scope of this article to set forth in detail the physical principles on which the constructions of the different sound-generating devices are based. However for the foregoing reasons it seems imperative to discuss critically those types of sonic and ultrasonic generators which have been used successfully for colloid work. It may be added that the patent literature contains a great number of grossly exaggerated and misleading claims; it is therefore disregarded in this review. Four main groups of sound generators will be discussed, and their usefulness for special purposes will be indicated.

(a) **Piezoelectric Sound Generators**, advantageously used in the frequency ranges from 100,000 to 1,000,000 cycles a second. The upper limit is determined by the usefulness for colloid-chemical work and not by the possible range of such generators (which may be built for frequencies up to 10^9 cycles per second).

(b) **Magnetostrictive Sound Generators**, successfully used in the frequency range between several thousand and about 50,000 cycles a second, *i.e.*, between higher audible sound and lower ultrasonic frequencies.

(c) **Electromagnetic Sound Generators**, useful mainly in the range of lower and medium audible sound frequencies.

(d) **The Gas Current Vibration Generator**, a device useful only in gaseous systems. Its range extends from very low (infra-acoustic) up to high ultra-acoustic frequencies.

A discussion of the engineering aspects involved in the construction of such generators must here be omitted completely. Readers interested in constructing such generators will find below some of the pertinent references. Some generators are now commercially available, but the author has no personal experience with them.

Piezoelectric Generators. The piezoelectric sound generator is a device for transforming high-frequency electric oscillations into mechanical oscillations by making use of the piezoelectric effect. Piezoelectric generators were the first used for colloid work and are still most commonly used.

If pressure is applied to a crystal belonging to a crystal system without center of symmetry, certain crystal faces become electrically charged; conversely, if a potential difference is applied to certain faces of the crystal, it contracts or expands according to the direction of the applied voltage. These phenomena are called piezoelectric effects. For technical and economic reasons, only discs and plates cut in a suitable manner from large quartz crystals have been used as piezoelectric oscillators for work on colloids.

If an alternating electrical field is applied to such a quartz plate it contracts and expands periodically—it vibrates. The frequency of these vibrations is, of course, that of the electric field applied. At a given field strength the vibrations become much stronger if the natural mechanical frequency of the disc coincides with the frequency of the applied electric field, *i.e.*, if the quartz vibrates in resonance. Under these conditions electrical energy can be transformed efficiently into mechanical oscillations. As the frequency of the natural mechanical oscillations of a solid body depends upon its shape and size, it is easily understood that the dimensions of the quartz disc determine the frequency of the electric field which should be applied to achieve maximum effects through resonance. Harmonic oscillations of higher frequency can be stimulated; they are, however, not nearly as powerful as those at the natural fundamental frequency. Circular quartz crystal discs 60 to 80 mm in diameter have mostly been used. Their thickness was usually between 7 and 14 mm, corresponding to frequencies from 150,000 to 300,000 cycles per second. Unfortunately, large quartz discs are rather difficult to obtain and are expensive. For detailed information on the physics and technology of piezo-quartzes the reader may consult the monographs of Scheibe,²³⁰ and Vigoureux.²⁵⁸

If an oscillator vibrates in air the energy transmission from solid to gas is very poor. Since one cannot cause a quartz oscillator to vibrate really strongly—for it would crack under the stress associated with greater amplitudes—the use of the other devices, listed below, for work on gaseous systems is indicated. If, however, a quartz crystal vibrates in a liquid, *i.e.*, in a medium of a specific gravity and sound velocity similar to the quartz oscillator itself, then the energy output may become rather high even with small amplitudes. For most work on colloids one makes use of this and immerses the quartz oscillators several centimeters deep in a bath of transformer oil. Vibrations transmitted into the oil are easily conducted to any other liquid or solid system dipped into the vibrating oil. The use of oil has the additional advantage that rather high voltages can be applied to the quartz oscillator, without the danger of sparking, etc. If properly handled, oscillators seem to last indefinitely, provided they were carefully selected (free from twinning, impurities, etc.). The author and his collaborators have used the same quartz plate without serious difficulties over a period of several years for several thousand hours.

The high-frequency electrical oscillations to activate the crystal are generated by a suitable electronic oscillator with an energy output of several hundred watts or more. The sender is coupled to the quartz plate by means of a Tesla coil; the plate is fixed between suitable electrodes in a bath of transformer oil¹ (Fig. 1).

FIGURE 1. Piezoelectric sound generator.

Descriptions of 2-KW transmitters have been given by Wood and Loomis;²⁵⁶ Freundlich, Rogowski and Sollner;⁷⁶ and others. (See, *e.g.*,¹⁶² compare, *e.g.*,^{6, 7, 50, 91, 106, 191})

The secondary high-frequency voltage which is applied to the quartz oscillator is varied according to the desired effect. For fast emulsification Freundlich, Rogowski and Sollner⁷⁶ applied 30,000 to 40,000 volts. The energy consumed under these conditions by the quartz oscillator, the electrode system, and the oil bath—as measured calorimetrically—was 250-300 watts, for stronger effects up to 500 watts. How big a fraction of the calorimetrically measured energy is available as sound energy cannot be determined accurately; it depends on the frequency, the electrode system, etc. The difficulty of these measurements (see, *e.g.*,¹⁸⁵) is one among several reasons why hardly any information exists concerning the influence of the frequency under comparable energy conditions.^{57, 71}

Small ultrasonic quartz generators for colloid work have been described in several instances. (See, *e.g.*,¹⁷⁹). The writer considers them to be unsatisfactory for investigative or preparative purposes, for the energy output is so small that their usefulness is much limited. The time required to obtain the effects which may be had within seconds with more powerful generators is inordinately long. It also seems doubtful whether such effects as the formation of fogs, or the dispersion of solids, can be achieved with such outfits at all. However, it seems probable that

fairly small high-frequency generators may become really useful if used with more efficient quartz vibrators than those used so far for colloid work. (See below). With the conventional quartz crystals and quartz mountings, generators with less than 300 watts high-frequency output and quartzes of less than 60 mm diameter are not recommended.

The mounting of quartz plates for colloid work was described by Wood and Loomis;²⁵⁶ in detail by Freundlich, Rogowski and Sollner,⁷⁶ Claus,^{53, 57} and others.^{4, 6, 7, 106} One such electrode system is shown in Fig. 2. The quartz crystal is

FIGURE 2. Quartz oscillator and electrode system, about one-half actual size.

best laid upon a thick piece of lead, the surface of which is ground plane; this serves as the lower electrode. The upper electrode is formed by a brass ring, the best dimensions of which are determined empirically. It is held in position by glass hooks provided with springs. The electrodes are connected to the secondary side of the Tesla coil. Some investigators prefer the use of quartz vibrators the circular faces of which are metallized, mounted in similar electrode systems.

If a crystal, radiating upward, vibrates at low energies in the oil bath, a slight tremor of the surface of the oil is seen; at greater energies a mound of oil is raised above the surface over the crystal; its height varies from bare visibility to several centimeters. At still higher energies (those useful for fast emulsification) the oil mound breaks up forming a fountain of oil 6, 8, or more centimeters high. This oil fountain is due less to "radiation pressure," than to a peculiar pumping action of the vibrating oscillators.¹⁴³

It is practically never possible to perform experiments on colloids directly in the oil bath, chiefly because of the danger of sparking, which could easily damage the crystal. One usually dips a test tube containing the system under investigation into the oil fountain, and thus exposes it to the action of the sound oscillations. The containers used for this purpose should be of strong and fairly thin glass. The wall thickness is not nearly as critical a factor as one might expect *a priori*, for the sound waves are not transmitted as longitudinal waves through the glass (if this were the case its thickness would be very critical), but transverse vibrations set up in the walls of the container. These in turn are transmitted to the liquid inside.

Gruetzmacher⁸⁴ and others have constructed electrode systems in which only one of the circular faces of the quartz vibrator is in contact with a medium of very low acoustic impedance (air). This results in an almost complete reflection of the sound waves at the air side of the quartz; they are in phase with those radiated from the other side of the vibrator and the useful energy output is thus almost doubled.

Gruetzmacher⁸³ also describes a piezoelectric quartz, shaped like a spherical concave lens, which brings the ultrasonic waves proceeding from the vibrating quartz surface to a focus. Gruetzmacher was able in this manner to concentrate the energy at the focus to more than 100 times the value near the vibrating quartz itself. So far use has not been made of such improvements for work on colloids. Upon their successful application will depend how far piezoelectric sound generators will ultimately be used for laboratory or industrial work.

Magnetostriction Generators. The magnetostriction generator is a device to transform alternating electric currents into sound vibrations, making use of the magnetostriction effect as first described by Pierce.^{170, 171, 172, 173}

If a rod or tube of ferromagnetic material is brought into a magnetic field parallel to its axis, its length is changed slightly. This change of length is independent of the sign of the field, and may be either a decrease or increase. This depends on the nature of the material, its previous treatment, the degree to which it was previously magnetized, the applied field strength, etc. This effect is known as "magnetostriction." The changes of length so produced are of the order of magnitude of a few parts in a hundred thousand with easily produced field strengths. Besides pure nickel, various nickel alloys (Invar, Monel metal, etc.) and occasionally cobalt are used.

The basic principle of all magnetostriction oscillators is this: if a nickel rod, for example, is brought into an alternating magnetic field it is shortened periodically by magnetization. It is easy to see that if the rod is not previously magnetized it will vibrate with double the frequency of the alternating field. If, however, it is suitably premagnetized, the mechanical change in length will be in step with the alternating frequency. If there is resonance between the natural elastic period of the nickel rod and the frequency of oscillations caused by the magnetic field, the amplitude of the oscillations will be at a maximum. The alternating magnetic field used in the magnetostriction sound generators is, of course, produced by an alternating electric current of the same frequency.

The fundamental frequency, ν , of a rod is given by

$$\nu = \frac{V}{2L}$$

V being the velocity of sound in the rod, and L , its length. For colloid work harmonics are rarely used. With a sound velocity in nickel of about 5,000 m/sec, the length of the rod or tube is about 50 cm for a frequency of about 5,000 cycles per second, 12.5 cm for about 20,000 cycles a second, and so forth.

To permit such a rod to vibrate freely at its fundamental frequency it is held at its middle, which leaves the ends free to vibrate. The exciting magnetic field, or in the case of the more frequently used generator with pre-magnetization, the two magnetic fields are applied by the use of suitable coils, or magnetic yokes, or a combination of the two.

For practical purposes, instead of nickel rods, nickel tubes are used which are closed at the upper end and cooled from below with a stream of water. They are supported in the middle by a rubber ring carrying the reaction vessel. Many investigators split the lower half of the nickel tube to reduce eddy currents. Suitable arrangements have been described by Gaines;⁷⁷ Chambers and Gaines;⁴⁶ Chambers and Flosdorf;⁴² Freundlich and Gillings;⁷¹ Clair;^{48, 49} and many others.¹⁹⁰ Fig. 3 shows the construction of a laboratory model described by Chambers and Flosdorf.

The magnetostriction sound generators are used not only in liquid but also in gaseous systems. In the latter case the vibrating nickel tube carries a heavy, piston-like end-plate of large diameter to facilitate the transmission of energy into the gaseous phase.

The relatively great length of the sound waves produced by the magnetostriction sound generators is one of their main disadvantages for work in liquid systems, as it is of the same order of magnitude as the dimensions of convenient containers. Consequently the action of the sound waves, which is strongest in the nodes and loops of stationary waves (see below), is more or less confined to a few planes or points many centimeters apart; such points may not properly occur at all in small systems.⁷¹

An advantage of the magnetostriction oscillators is their relatively simple and cheap construction and the absence of the costly quartz crystals. They have the

FIGURE 3. Magnetostriction sound generator.

additional advantage that the oscillator itself—the vibrating nickel tube—may in most cases be brought in direct contact with the substances to be treated without the interposition of another medium. Thus the unavoidable but great losses of vibrational energy suffered by dissipation and reflection in the oil bath of the piezoelectric sound generators is avoided here.

It seems likely that magnetostriction generators will at least partially displace piezoelectric oscillators for colloid work. Their efficiency can be increased greatly by the use of some sound concentrating devices, such as described by Chambers and Gaines;⁴⁶ one also could try the use of hollow-ground end-plates of the nickel vibrator similar to Gruetzmacher's⁸⁸ quartz crystal lenses.

Electromagnetic Generators. The electromagnetic sound generators have so far been used in only a few cases for colloid work. Since their frequency is entirely in the audible range, rather large amplitudes are necessary to produce the same quantity of sound energy. Their effectiveness reported for liquid systems, at least in some cases, is not due to typical sound action.⁷¹

Chambers⁸⁷ describes two types of oscillators, one of conventional electromagnetic design, and one of the Fessenden type which he used for the treatment of milk.

(See also ²²⁶). Their description by Chambers ³⁷ is quoted here. "1. Electromagnetic oscillators available were similar to those used in submarine communication and echo depth sounding consisting essentially of a heavy, loaded, steel membrane actuated by alternation in an electromagnetic circuit." (See Fig. 4a) "Three oscillators of this type were available with resonant frequencies of approximately 1200, 2160, and 3000 cycles per second respectively. Power was supplied from appropriate motor driven generators at one-half the oscillator frequency since the diaphragms were non-polarized. Input of electrical energy in each case was from 400 to 600 watts, depending somewhat on the loading conditions. Actual output of acoustic

FIGURE 4. Two types of electromagnetic sound generators.

energy at 1200 cycles was approximately 175 watts while the electrical efficiency of the other oscillators was considerably lower. In fact the acoustic output of the 3000 cycle apparatus was so low that no satisfactory tests could be made at that frequency.

"2. Oscillators of the Fessenden type were also used, in which the vibrating membrane is fixed to a copper tube, the whole being polarized by an inciting current of about 2.75 amperes. Movement of the diaphragm depends on reversal of eddy currents in the copper sleeve induced by current oscillations in the activating coil." (Figure 4b). "Consequently the frequency of vibration is equal to the frequency of the activating current and not twice that value as in the electromagnetic oscillators. Two oscillators of the Fessenden type were used, one with a resonant period of about 1090 cycles, the other with resonant periods at 360 and about 610 cycles. Power input was variable up to 2200 watts. The electrical efficiency was about 45 per cent except at the 610 cycles resonance point where the power ratio was somewhat lower. . . . Accessory equipment . . . consisted of a heavy bell metal cover, tinned, bolted to the margins of the steel diaphragm. Two marginal openings were provided, one for the ingress or egress" of the liquid to be irradiated and the other opening to "enable elimination of an air pocket from the chamber formed between cover and diaphragm. In addition a central opening was provided as an outlet or inlet for" the liquid. ". . . This opening passed centrally through a stainless steel 'anvil' or reflecting plate capable of micrometer adjustment in such a way that the layer of 'liquid' between anvil and diaphragm could be reduced to any desired value up to one-half inch in steps of .001 inch. . . ."

Clair ^{48, 49} describes briefly an electromagnetic generator, developed for a study of the coagulation of smoke; it is claimed to be very efficient. So far Clair's generator has only been tested in gaseous, not in liquid systems. Clair's ⁴⁹ description follows: "The vibrating element consists of a solid cylinder of Duralumin supported by an annular web at its midsection and free to vibrate longitudinally as a free-free bar. On the upper end is a driving ring which projects into the radial gap of a pot magnet. It is excited by a high frequency current which flows through a coil wound

around the center pole of the magnet adjacent to the driving ring. This current induces in the driving ring a much greater current which interacts with the magnetic field to cause an alternating force to be applied to the vibrator, just as the current in the voice coil drives the diaphragm of a dynamic loudspeaker. The vibrator is made self-exciting by means of a built-in electrostatic pick-up unit which causes the vibrator to initiate the electrical oscillations which drive it." "... The vibrator executes simple harmonic motion even at the maximum amplitude. ..."

"... Sound energy is radiated from the lower face of the vibrator into the cylindrical chamber" containing the gaseous system to be irradiated.

Freundlich and Gillings⁷¹ tried with little success the vibrating mechanism of an automobile horn with a maximum input of 100 watts.

Since only a few investigators have used electromagnetic sound generators it is difficult at present to appraise their merits justly. One has the impression that they are very promising in the treatment of gaseous systems. The effects obtainable in liquid systems seem to be moderate at best. One is not sure that the effects are entirely due to typical sound actions, and not, at least partially, the result of immediate mechanical action. The amplitudes which are necessary at low frequencies in order to produce an intense sound field are so large that various types of effects due to gross stirring may occur, as indicated by the results of Freundlich and Gillings.⁷¹ If it should be found possible to operate electromagnetic sound generators really efficiently in liquid systems, it seems likely that this method could find wide industrial application.

Gas-current Vibration Generators. For attaining considerably greater energies of vibration in air than those obtainable with conventional or Galton whistles, Hartmann^{85, 86, 87, 88, 89} constructed the gas-current vibration generator. It is based on an effect described first by Mach and Salcher.¹³¹ If a current of air is allowed to issue from a nozzle at a speed greater than sound velocity, *i.e.*, under a pressure of 0.9 atm or more, a periodic structure is formed in the air stream. The pressure, *P*, varies periodically at different distances from the mouth of the nozzle, *D*, as indi-

FIGURE 5. Gas-current sound generator.

cated in the upper half of Fig. 5. The regions of rise of pressure are intervals of instability in the jet. They make possible the production of sound waves, when a hollow body, serving as an oscillator, is brought into these regions of instability. (Fig. 5, lower half). The hollow oscillator is periodically filled with an overpressure of air and in the intervals this air is forced out again, whereby an oscillation is pro-

duced. The frequency of these sound waves is determined by the dimensions l and d of the hollow oscillator, and its distance x from the nozzle D . For example, if the diameter of D is the same, d , as that of oscillator, and if $d = l = 4$ mm, the frequency is 11,000 to 17,000 cycles per second, according to its distance x from D . (See Fig. 5). The frequencies obtainable with Hartmann's sound generator range from the infra-acoustic range, through the whole acoustic range, up into high (500,000 cycles per second) ultrasonic frequencies. Hartmann⁸⁹ estimates that 5 per cent of the power input is transformed by this gas-current vibrator into sound energy. Sound outputs of 100 watts and more have been claimed for the apparatus.

On account of its simplicity and the lack of expensive auxiliary equipment—all that is necessary is a source of compressed air—the gas-current vibrator generator seems to be destined to play an increasingly important role in colloid work in gaseous systems, particularly for industrial purposes. Certain difficulties have been pointed out by Clair.⁴⁹

The Main Effects Caused by Sound Waves in Physicochemical Systems and the Mechanisms which Bring Them About

We have mentioned before that the most characteristic actions of intense sound waves are the disintegrating and ponderomotive effects: emulsification, formation of fogs, dispersion of solids, liquefaction of gels, etc. on the one side, and accumulation, coagulation, and orientation on the other. Besides these main phenomena there are several more effects which must be discussed, at least briefly: the degassing of liquids, thermal effects, the acceleration of crystallization, and finally the influence of sound waves of high intensity upon chemical reactions. Most of the phenomena mentioned were first observed by Wood and Loomis²⁵⁶ and described in their pioneering paper.

Emulsification and Emulsions. If a test tube containing water and mercury, or water and an immiscible organic liquid, is dipped into the oil fountain of a piezoelectric sound generator, or if the same two phase systems come in contact with the vibrating nickel rod of a magnetostrictive sound generator, emulsification occurs at once. Grey clouds of very fine mercury droplets are thrown into the water from the water-mercury interface; in oil-water systems white clouds of dispersed water or organic liquid, respectively, are produced where the two liquids meet; soon more or less concentrated emulsions are obtained. In non-protected systems 6 g of mercury per liter and 50 to 60 g of benzene or similar substances may be dispersed in one or two minutes, and these concentrations do not increase on further irradiation. In the presence of suitable emulsifiers very high concentrations can be obtained.

In 1929 Richards¹⁸⁶ emphasized the differences in the nature of the emulsification of mercury and in the dispersion of organic liquids in water. For liquid and molten metals the mechanism of dispersion in water or organic liquids, according to Richards¹⁸⁶ see also 217 is as follows: when the vessel containing the metal and the water is brought into the oil fountain, violent transverse vibrations are set up in the walls of the vessel; these vibrations pump small quantities of water into the liquid metal; the water droplets rising in its interior reach the interface metal-water covered with a thin film of metal. When this film breaks, a cloud of minute metal droplets is thrown into the water. This process, as described for the macro-interface metal-water, obviously occurs also between the water droplets in the interior of the liquid metal, thus accentuating the effect. Sollner²¹⁵ irradiated a low-melting alloy-water system and cooled it during the irradiation. The metal solidified under these conditions is sponge-like, as is apparent from Fig. 6, showing its cross-section and its surface, which is covered with little blisters. For a reason which will be understood later, it must be stressed that this dispersion of metals occurs equally well *in vacuo* or under high external pressure.²¹⁷ The mechanism of the formation of Hg-sols by sound waves is basically the same as by normal mechanical dispersion,

which was investigated by Nordlund;¹⁵⁴ Kremnew¹¹⁹ has elaborated on this point.^{see also 192}

Now let us turn our attention to the mechanism of emulsification in oil-water systems.²¹⁶ The facts concerning emulsification in non-metallic systems, as described first by Newton Harvey,⁹¹ are as follows. Emulsification occurs neither *in vacuo* nor when sufficiently high outside pressure is applied, the liquids in the latter case being gas-free or saturated with gas at a lower pressure only. This rule applies equally well in the presence of even the best emulsifiers, where mere shaking

FIGURE 6. Emulsification of a metal by ultrasonics. A low-melting alloy solidified during irradiation. About twice actual size.

may easily produce stable and fine-grained emulsions.²¹⁶ When the system is in equilibrium with a gas phase, emulsification always occurs on irradiation, provided this pressure is neither too high nor too low. The lower limit is much more sensitive; in toluene-water systems, for example, an absolute gas pressure of at least 100 mm of mercury is necessary. How striking the effect of the gas pressure is may be seen in Fig. 7; the test tube at the left contains air at atmospheric pressure, the test tube at the right is thoroughly degassed.²¹⁵

Next we must turn to the question of how the sound waves cause what at first sight appears to be such complicated phenomena, the effects being substantially the same whether performed at a few thousand or at a million cycles a second. According to Chambers and Gaines,⁴⁶ and Bondy and Sollner²¹⁶ the explanation is as follows. A sound wave travelling through a liquid compresses and stretches it periodically. If the stretch is moderate and the irradiated liquid is free of gas, nothing spectacular occurs; but if the liquid is saturated with gas, gas bubbles appear, as was shown in detail by Boyle¹⁸ and Newton Harvey⁹¹ and their co-workers (see below, p. 363). What happens if the liquid is stretched unduly was described nearly seventy years ago as a curiosity by Kundt and Lehmann¹²⁴ (working at low fre-

quencies). They said: "While the whole system was vibrating violently the water close to the end of the vibrating rod turned turbid during the vibration. Since it was entirely free of air, these small bubbles causing the turbidity could only be due to the disruption of the water under the influence of the intense vibrations." When irradiating with sound waves of sonic⁴⁶ or ultrasonic²¹³ frequencies carefully de-

FIGURE 7. Emulsification by ultrasonics. The influence of the presence of a foreign gas upon emulsification. About one-third actual size.

gassed liquids, such as benzene, toluene, or water, zones of a slight and somewhat glittering opacity were always observed, although no bubbles rise to the surface; a hissing noise is heard under these conditions.

Thus it is clearly indicated that the liquid disrupts under the stretch of sound waves; a high hydrostatic pressure prevents this disruption and thus the subsequent phenomena. If the same experiment is performed in a vacuum even at low energies, the liquid bubbles and boils but no hissing noise is heard. Under neither of these conditions does emulsification occur. Strong mechanical action by ultrasonics is always accompanied by a hissing noise, its loudness being so characteristic that it was used by the author and his collaborators as a very convenient and rather accurate indicator of their efficiency. It is apparent that, although the formation of cavities does not give rise to destructive action, their disappearance, always connected with the hissing sound, does.

Lord Rayleigh¹⁸³ calculated the pressures which may occur when a vapor bubble collapses in a liquid and found that many thousands of atmospheres may be obtained locally in this way. These enormous local stresses, of course, can cause all kinds of intense mechanical effects. In engineering the entire phenomenon involving the formation of cavities and their violent collapse due to outside pressure is called "cavitation." This term will be used in this sense.

It can easily be demonstrated that the collapse of steam bubbles produces emulsifi-

cation when occurring at the interface of two liquids; this collapse of the steam bubbles is always accompanied by a rattling sound,²¹⁶ the same as in the case of emulsification caused by cavitation due to sound waves.

Thus, we may safely conclude that the emulsification by ultrasonics is due substantially to "cavitation," as defined above.^{215, 216} This explanation accounts readily for the fact that no emulsification occurs in a vacuum or when a high outside pressure is applied. In a vacuum cavities may be formed, but lack of outside pressure prevents their violent collapse. On the other hand, a sufficiently high pressure prevents the formation of cavities. (The prevention of cavitation by the application of outside pressure is well known in engineering.)

Disruption due to cavitation occurs in an irradiated system preferentially at weak spots, where the energy of disruption is relatively low. The disruption is favored at oil-water interfaces,^{213, 216} a fact which probably contributes to the remarkable speed of emulsification; thus cavitation is favored where emulsification may occur. Similarly dissolved gases may act as "weak spots";²¹⁶ they are driven out by irradiation, forming small bubbles, thus favoring cavitation.

It seems permissible to visualize cavitation which leads to emulsification (and other destructive processes) as a very violent hammering of the collapsing cavities, occurring at the phase boundary.

It is always observed that considerable, often turbulent stirring occurs if the ultrasonic irradiation is strong enough to cause rapid emulsification. There is first the collapse of cavities, which causes violent stirring near the phase boundaries liquid-liquid and liquid-gas; next we have to consider the irregular reflection of sound energy at the same places; and finally we must remember that the walls of the container holding the irradiated system vibrate in an irregular manner; thus they cause gross stirring which is frequently made conspicuous by the formation of vortices.

According to Smith,²⁰⁷ the oscillation of gas bubbles in a sound field is the cause of many of their mechanical actions in liquids, such as emulsification. There seems little doubt that the ideas of Smith deserve very careful consideration; if properly coordinated with the cavitation theory of emulsification, they will considerably deepen our insight into the mechanism of emulsification. The ideas of Marinenco^{133, 134, 135, 137, 138, 139} concerning the mechanism of emulsification are rather detached from any observed facts.

The influence of pressure and vacuum is not observed when dispersing liquid metals, since, as already mentioned, their dispersion is not due to cavitation.

Emulsions prepared by sound waves do not show any distinguishing features. The concentrations and particle size vary greatly according to the materials used, the intensity of the irradiation, its duration (unless a stationary state is reached), and the size and shape of the reaction vessel.

The best-investigated case among the metal dispersions is that of mercury.^{54, 218, 220} The concentrations obtained by Bondy and Sollner,²¹⁸ in samples of a few ml and using high sound intensities, were about 6 gm/l for water and aqueous solutions of stabilizing electrolytes, and about 60 gm/l in aqueous systems containing such stabilizing agents as lysalbinic acid. The stationary concentration which does not increase on longer irradiation was reached in about one minute. The particle size varied from the ultramicroscopic range to diameters of 5-8 microns, larger particles settling out rapidly. Quantitative particle size distribution measurements were given by Bondy and Sollner.²¹⁸

With organic solvents (cyclohexane, petroleum ether, benzene, toluene, xylene, ether, acetone, chlorobenzene, carbon disulfide) at room temperature only extremely dilute, rather unstable emulsions of mercury were obtained. At low temperatures, near the melting point of mercury, more concentrated emulsions may be obtained. Their stability is also greater, if they are kept at these lower temperatures.

With the alcohols the mercury concentration rises from 2 per cent with methyl alcohol to 18 per cent with isoamyl alcohol, etc. Generally in viscous liquids, such as glycol, glycerin, and benzyl alcohol, rather concentrated emulsions may be obtained (10-20 per cent). Particle size distributions were measured in many liquids by Bondy and Sollner.²¹⁸ In the presence of stabilizers, such as rubber (in benzene), highly concentrated and very stable emulsions may be obtained.

A very interesting and still unexplained influence of gases on the stability of mercury emulsions was found. It is possibly of fundamental interest. In the absence of gases the amount of mercury dispersed in water by ultrasonic waves is very small, about 0.5 gm/l; this is less than 10 per cent of the concentration which is obtained under otherwise identical conditions in the presence of air. The gas-free emulsions are very unstable; after a short time the water is quite clear again, all the disperse phase having settled down and united with the bulk mass, which then shows its normal reflecting surface. When gases are present (air, N_2 , O_2 , H_2), ultrasonics rapidly produce fairly concentrated and much more stable emulsions. The droplets, after having settled down, do not coalesce, but form a gray sediment which coalesces with the bulk of the mercury so slowly that it does not entirely disappear even after many days. This sediment may be redispersed merely by shaking. Since this effect is found whether either hydrogen or oxygen is present, chemical action may be excluded. Feebly adsorbable electrolytes do not influence this effect of gases. More strongly adsorbable electrolytes render the gas influence less distinct. In the presence of true protective agents, such as soaps, gelatin, or lysalbinic acid, the effect of gas disappears entirely. In liquids, such as butyl alcohol, amyl alcohol, nitrobenzene, aniline, etc., the effect was especially marked. Although the emulsions in these liquids show only a small difference as to their concentration shortly after irradiation, the stability in the gas-free systems is much less (Table 2).

Table 2. Change of Concentration of Hg-Emulsions in Course of Time²¹⁸

| Time after Emulsification | Disperse Phase in gm/l | | | |
|---------------------------|------------------------|-----------------|----------------------------|-----------------|
| | In Nitrobenzene | | In <i>n</i> -Butyl Alcohol | |
| | In Air | <i>In Vacuo</i> | In Air | <i>In Vacuo</i> |
| 1 minute | 8.4 | 6.4 | 7.6 | 6.0 |
| 30 minutes | 6.4 | 1.6 | 3.5 | 1.2 |
| 3 hours | 5.0 | 1.3 | 2.4 | 1.5 |
| 16 hours | 4.1 | 0.9 | 2.0 | Nearly clear |
| 48 hours | 3.0 | Nearly clear | 1.6 | clear |

Kremnev's¹¹⁹ assumption that gases favor the process of dispersion cannot explain this difference in stability. The stabilizing effect of gases is presumably general.^{192, 217, 218} Cone, Tartar and Taylor⁵⁵ have found that Zsigmondy gold sols change their color to a brighter red and have a higher precipitation value after being saturated with gas; hydrogen and oxygen exert their action in the same direction. (For further references see²¹⁷.) A more detailed investigation of the stabilizing effect of gases seems very desirable.

Other metals besides mercury may easily be dispersed if their melting point is low enough. They are dispersed only in the liquid state; solid metals cannot be dispersed. The alkali metals form concentrated emulsions in organic liquids, such as paraffin oil and xylene.^{54, 218} Those in paraffin oil have very intense colors: reddish violet in the case of sodium, bluish green in that of potassium.²¹⁸ Concentrated emulsions in aqueous and non-aqueous liquids may be prepared with Wood's metal.^{218, 256} Very finely grained emulsions of this metal are obtained in bromonaphthalene and tetrachloroethane. When the coarser particles have settled a brown, stable, truly colloidal solution remains.

Oil in water and water in oil emulsions were produced with many pairs of incompletely miscible liquids.²¹⁸ The limiting concentrations in the water phase are 4-5 per cent with such substances as benzene, toluene, xylene, aniline, nitrobenzene, etc. The water-in-oil emulsions are in most cases very dilute. In properly protected systems, *e.g.*, in the presence of soaps, 75 per cent emulsions of oil in water are readily obtained. Particle size distribution measurements have been published by Bondy and Sollner.²¹⁸ (Further references on emulsification and emulsions: ^{33, 37, 120, 147, 149, 178, 189, etc.}) Chambers^{37, etc.} has suggested the homogenization of milk to induce soft curd character by intense sonic treatment. This seems to be the first attempt to use the emulsifying action of sound waves on an industrial scale.

Formation of Fogs. The formation of fogs, *i.e.*, the "atomization" of nonmetallic liquids by ultrasonics, was first described by Wood and Loomis.²⁵⁶ With fairly volatile liquids, such as benzene, toluene, water, etc., fog formation is best shown by irradiating a beaker containing a little of one of these liquids with sound waves of fairly high intensity. The beaker fills rapidly with a white cloud; this fog is in a continuous turbulent motion.

To produce fogs of more viscous liquids, *e.g.*, of transformer oil, another arrangement must be used. A test tube about 2.5 cm in diameter is drawn out in the middle to form a thin-walled constriction of about 7 mm diameter. When it is dipped into the oil bath of an ultrasonic generator, the oscillations of the glass at the constriction are very vigorous. If a little oil is now applied to the outside of the tube above the constriction, it spreads over the surface and seems to be thrown out in jets of spray, and a dense cloud gathers about the tube. Close inspection shows that the oil on the collector gathers in more or less regular rings which form dots here and there, and the jets of spray seem to be shot out from these dots.²⁵⁶

The strong heat effects (see pages 367 to 369) always connected with intense irradiation might be supposed to cause the formation of fogs by a mechanism of evaporation and immediate recondensation. But, as shown by the author,²¹² this is not the case, for if solutions containing a non-volatile compound, such as a dye, are used, colored fogs are readily formed and hardly any residue of the non-volatile substance is left after the whole liquid has been dispersed into the air. Thus, "temporary" evaporation is excluded as the cause of formation of fogs.

Another possible explanation might lie in the fact that, during irradiation, all liquids form mounds or fountains which throw drops of the liquid into the air.²⁵⁶ However it was demonstrated that this phenomenon is in no way directly related to the formation of fogs.²¹²

The movement of the fog away from the collector, as if coming from jets, is due to air currents¹⁴³ set up in the neighborhood of the vibrating collector; these air currents are strong enough to blow the flame of a micro-burner horizontally sideways when it is brought close to the collector.²¹² The air currents, however, do not explain the formation of the fog droplets.

An indication as to the true mechanism of the fog formation may be seen in the fact that, if the intensity of irradiation is increased, the surface of a liquid always becomes rippled as if it were being hit from above, just before fog formation sets in. It was previously mentioned that phase boundaries are frequently a preferred place of cavitation; for the case of the air/liquid interface, this was demonstrated in emulsification experiments by Sollner and Bondy.²¹⁹ It, therefore, seems very likely that fog formation is also due to cavitation. This would be proved if the effect disappears when cavitation is rendered ineffective. Obviously, the pressure method cannot be applied since the surface, at which the fog is formed, is in contact with the gas by means of which pressure can be applied, and saturation in the liquid film with which we are concerned occurs much too rapidly to allow conclusive experiments.²¹² The vacuum method, however, can be used. (Liquids having a low vapor pressure are best suited for this, because they exclude minor complications

caused by the vapor pressure of the irradiated and consequently heated liquid.) No fogs are formed if the liquid was first carefully degassed and sealed in test tubes *in vacuo*; this holds true even with such strong irradiation that a considerable fountain is formed in the liquid and large drops abundantly thrown out from its surface. This surface *in vacuo* also lacks the characteristic rippled appearance always associated with fog formation. One may therefore safely conclude that the formation of fogs is due to the same mechanism as that producing all other disruptive and destructive effects in non-metallic systems, *i.e.*, cavitation.²¹²

In the manner described by Wood and Loomis many organic liquids have been successfully "atomized": benzene, toluene, tetralin, decalin, paraffin oil, and many others.

It has not been possible to produce fogs which are stable for more than a very few minutes, since the particles are too large. For this reason they have not been investigated extensively. Ultrasonics actually do not at present provide a really satisfactory method for the preparation of fogs: other methods yield them much more readily and with much smaller particles. The converse phenomenon, the coagulation of fogs by sound waves, which was very extensively studied, will be discussed below.

Dispersion of Sediments, Precipitates and Gels. The peptizing action of ultrasonic waves on gels, gel-like substances, precipitates and sediments has been extensively investigated. All such systems contain pre-formed particles of colloidal or semi-colloidal size, and it has been found that these particles may be separated from one another readily by the action of audible and inaudible sound waves. The preparations made by sound action do not show any special features; the sound waves act merely as a mechanical dispersing device. However, the sound method of dispersion and peptization of sediments, precipitates and gels undoubtedly offers many advantages to the investigator in the field of colloids on account of the cleanliness and good reproducibility of this method and the small quantities of materials necessary.

Freundlich and Sollner⁷³ have demonstrated that the peptizing action of sound waves is due to cavitation. Neither under a high pressure nor *in vacuo* is peptization ever observed.

Mention may also be made of two further points of importance in the peptization of gels: the vigorous movement to be seen in two-phase systems when irradiated, and the heat (see below) which is developed in many disperse systems. The gross stirring and the increase in temperature, of course, in many cases greatly increase the rate of peptization. That the same is true for the rate of reaction in heterogeneous systems in general ^{see e.g., 144} hardly needs to be mentioned.

Some of the reported cases of dispersion of precipitates, sediments and gels are: dyestuffs and pigments; ^{203, 247, 248, 249} metal hydroxides; ^{73, 74, 76, 193, 200, 201} starch; ^{158, 159, 160} carbon in aqueous alcohol; ¹⁹⁴ reversible liquefaction of thixotropic systems, mostly of metal hydroxides; ^{73, 74, 76, 198, 199} thixotropic silica gel; ^{70, etc.} the liquefaction of thixotropic gels gradually blends in the reduction of structural viscosity of similar but "liquid" systems. This problem will be dealt with in a separate section below, after the discussion of the dispersion of coherent solids.

The preparation of extremely fine-grained photographic emulsions of great sensitivity was reported by Claus,^{50, 52, 53} and Dangers,⁵⁶ who irradiated silver bromide emulsions during their preparation. Claus reported in detail on the properties of these photographic preparations. The mechanism of the action of the sound waves in this case is not definitely known. One would be inclined to attribute it to the general destructive and disruptive action of sound waves caused by cavitation; however, other suggestions have been made; the thermal effects (to be discussed below) associated with strong sound action have been strongly emphasized. Chemical activation (see below) may also come into play. (See, *e.g.*,^{140, 180, 181, 182}.)

At the end of this section we must mention some very important work by Claus. As will be seen in the next section, a satisfactory dispersion by sound waves of solids of great cohesion, *e.g.*, of metals, is at present a practical impossibility. To circumvent this difficulty Claus,^{51, 53} and Claus and Schmidt,^{54, see also 252} submit systems in which metallic precipitates are formed by electrolysis or chemical reaction during these processes to the action of strong ultrasonic waves. As cathode in the electrolysis process a noncorrosive metal, *e.g.*, stainless steel, is used, to which the products of the electrolysis adhere poorly. The freshly formed metal is torn off the electrode (undoubtedly by cavitation) and thus dispersed in the liquid. The authors cited report that they produced in this manner fine-grained dispersions of Pt, Au, Ag, Hg, Cu, Cd, Pb, Bi, Ni, Cr, Fe, Al. (It seems doubtful whether the dispersions of the less noble metals should be considered as being of a purely "metallic" character.) The Hg emulsions produced by the method of Claus were much finer-grained than those produced by dispersion of the bulk phase.⁵⁴

Dispersion of Solids in Liquids. The first to try the dispersion of coherent solid bodies by ultrasonic waves was Richards;¹⁸⁶ he reports unsuccessful attempts to disperse solids (glass, quartz) in liquids. Rschevkin and Ostrowsky¹⁸⁹ claimed to have dispersed tin, sulfur, bismuth, lead, copper and even silver. The "emulsions" of sulfur, tin, bismuth and lead are said to be true colloidal solutions with a particle size of about 10^{-6} cm.^{See also 223} Sollner,²¹⁴ in criticizing their work, pointed out that one can consider a solid body to be truly dispersed by sound action only if one starts out with clean surfaces, carefully freed of all adhering dust or foreign substance. This is conveniently done by irradiating the sample under investigation repeatedly in water for several minutes. When initially irradiated, nearly all solid substances show dispersion. The difference between those substances which really are dispersed and those in which only adhering material is torn off becomes apparent after three or four irradiations. The author's criterion of a true dispersion was that the seventh to tenth irradiation (of two minutes each) invariably yielded the same positive result.²¹⁴ With these proper precautions one finds that silver, tin, glass, quartz and marble are totally unaffected, even by prolonged, very intense irradiation. Fibers of glass wool are broken, asbestos is split into fibers, and even thin foils of metals may be torn apart; but a true dispersion, yielding colloidal or semi-colloidal suspensions, is never observed in these and similar cases. Examples of substances comparatively easily dispersed in water, yielding colloidal or semi-colloidal solutions, are (crystals of) mica, gypsum, steatite, hematite, sulfur, and graphite.²¹⁴ They are all substances of only moderate cohesion, which are easily split and broken.

The suspensions so obtained contain particles of different sizes, their diameter being from several microns down to colloidal size. In the cases of mica, steatite, hematite and graphite, for example, the suspensions were particularly rich in particles of truly colloidal and semi-colloidal dimensions. (For the dispersion of camphor and iodine see ²⁵².)

The concentration of these suspensions is generally rather low, unless the irradiation is continued for a considerable period; *e.g.*, a piece of steatite with an apparent surface of about 5 cm² yielded 8 mg of dispersed matter in 5 cc of water after two minutes of irradiation at as high an energy as could be applied. Hematite, with a surface of about 8 cm² gave 1 mg under the same conditions, the particles obtained being non-spherical and particularly small.²¹⁴ The amount dispersed depends upon the character of the irradiated specimen; well developed crystals are less liable to destruction.

The solid substance to be dispersed need not necessarily be of macroscopic size; suspended particles have been successfully dispersed. Even the particles of truly colloidal solutions may be broken down further by irradiation. The particles of a V₂O₅ sol prior to irradiation were truly colloidal in two dimensions, their length

being between 10-15 μ . After irradiation their length was less than 3 μ . In this and similar cases the effect is more pronounced, and is obtained in a shorter time, if the concentration of the irradiated sol is decreased. Substantially the same results are obtained with colloidal graphite suspensions. The number of particles visible with bright field illumination decreases on irradiation, while the number of particles visible in the dark field increases greatly. The increase in particle number continues, with further irradiation, after all particles visible in the bright field have vanished, thus indicating that particles truly colloidal in all three dimensions are further broken down.²¹⁴

The dispersion of solids in liquids was shown to be due to cavitation.²¹⁴

The status of the problem from the point of view of the colloid chemist can be summarized as follows. Sound action is capable of dispersing only solid bodies of moderate cohesion. Thin metal foils may readily be broken and torn into small fragments, but no true dispersion ensues.⁵¹ From the engineering literature we know that cavitation causes the corrosion of the propellers of steamships (for references see ²¹⁶), though we do not know yet whether this is due entirely to direct mechanical action; chemical factors (activation of oxygen, see below) may also come into play. Claus and Schmidt⁵⁴ have reported a corrosion of the edge of steel blades on prolonged irradiation with ultrasonics of high intensity; the brittleness of steel and the peculiar geometrical configuration of the cutting edge of a steel blade make it doubtful whether this corrosion would proceed very far. (See also the careful investigation of Schumb, Peters and Milligan²⁴⁴.) The limits of what can be achieved experimentally depend quite obviously on the intensity of the irradiation. The best chance to extend the sonic dispersion of solids probably lies at present in the use of sound concentrating devices, such as the quartz crystal lenses of Gruetzmacher.⁸³

Changes in the Anomalous Viscosity of Colloidal Solutions, Splitting of Macromolecules and Related Phenomena. The liquefaction of thixotropic gels^{73, 74, 76} was discussed in a previous section. This effect can be considered as an extreme case of change in anomalous ("structural") viscosity. "Fluid" systems the viscosity of which is decreased by sound waves were described by Szent-Györgi,²²⁹ and Szalay^{227, 228} (gelatin, starch, gum arabic); Kimura¹¹³ (gelatin, gum acacia, Na-stearate); Heymann¹⁰³ (methyl cellulose); Sibata^{205, 206} (rubber); Freundlich and Gillings⁶⁹ (gum tragacanth, gum arabic, gelatin, agar, cotton yellow, benzo-purpurin, Na-stearate, and Na-oleate); Schmid and collaborators^{233, 234, 240, 241} (polystyrene, polyvinyl acetate, polyacrylic acid esters, nitrocellulose, rubber, etc.)^{See also 61, 195, 196, 246} It may be worth while to note that the true viscosity of liquids and solutions showing normal viscosity, such as glycerin or its aqueous solutions, is not affected by sound waves.⁶⁹

Freundlich and Gillings have investigated the general problem carefully on a fairly broad basis.⁶⁹ Of all the classes of substances investigated by Freundlich and Gillings, the gums show the simplest behavior. Dilute solutions of gums, *e.g.*, gum tragacanth, are very viscous and show a small degree of structural viscosity. The quantitative relationship can easily be established with a Couette viscosimeter. By treatment with sound waves the viscosity and its anomalies are reduced; the gum solutions become less viscous and show smaller deviations from Poiseuille's law. To bring about these effects, short ($\frac{1}{2}$ to 3 minutes) irradiations suffice, of about the same intensity as those used for emulsification. The viscosity of the irradiated solutions rises slowly on standing, but does not reach the original value. By applying pressure it can be shown that this effect is due to cavitation; no change in viscosity occurs when a sufficiently high outside pressure is applied during irradiation.

The behavior of gelatin solutions is not so simple; 0.5 per cent solutions show a distinct structural viscosity. Irradiation for 1 to 3 minutes with ultrasonics of different intensity results in all cases in a marked decrease in viscosity, but of a fairly

complex nature. Freundlich and Gillings⁶⁹ find that weak irradiation, sufficient to reduce the viscosity at low shear rates, may have no great effect at the higher rates, whereas more intense irradiation effects an overall reduction of viscosity at all shear rates. The solutions recover their structural properties rapidly on standing. There appear to be two kinds of irradiation effects which seem to cause the anomalous viscosity of gelatin solutions. In the region of lower shear rates the resistance of the solutions to flow is probably bound up with gel formation; at the higher rates we have a closer approach to a viscous resistance, the gel structure is destroyed, and the behavior is similar to that of a non-gelating solution, like a gum. Experiments on the mechanism of the attack of the ultrasonics confirm this view. If cavitation is rendered ineffective *in vacuo*, or if cavitation is prevented by pressure, the anomalous viscosity of gelatin solutions is much less affected by ultrasonic irradiation, as described in detail by Freundlich and Gillings.⁶⁹ However some reduction in viscosity cannot be prevented in this manner.

The behavior of agar solutions is similar to that of gelatin. Schmid and collaborators^{233, 234, 240, 241} found a similar complexity of behavior in several other cases, cavitation being responsible for part of the effect. Schmid, who irradiated his samples for long periods—up to 3 hours—thinks that frictional forces resulting from the relative motions of a rigid network of macromolecules and the vibrating solvent may cause the breakdown of macromolecules.²³⁴ Some other valuable ideas concerning this problem have been published by Szalay.²²⁸ High polymers seem to be a fruitful field for further investigations. The problem of recovery should be studied further; it blends gradually with that of influencing polymerization reactions.

Different from that of the preceding groups is the behavior of certain dyestuffs. Solutions of cotton yellow, *e.g.*, have characteristic colloid properties, especially as regards viscosity and optical behavior. Dilute solutions show distinct anomalous viscosity and strong streaming double refraction. Both effects are certainly connected with the presence of rod-shaped particles which are visible in the ultramicroscope. The structural properties of the dye were found to be very sensitive to ultrasonic irradiation; a short irradiation of low intensity was sufficient to effect a complete reduction of anomalous viscosity. The optical properties of the solutions are changed parallel with the reduction of structural viscosity. Ultramicroscopic examination showed a uniform dispersion of needle-shaped particles in the original solution; after irradiation the long particles had disappeared, and a very fine dispersion of apparently isotropic particles remained; correspondingly, the strong stream double refraction of the original solution had disappeared after irradiation. There was but little recovery on standing. In this case the dispersing action was due to the collapse of cavities. Irradiation under pressure produced no change in viscosity and none in optical properties.

Benzopurpurin sols showed a decrease in particle size after fairly strong irradiation, but without change in viscosity. Freundlich and Gillings also investigated V_2O_5 sols and found no change in particle size or in viscosity. However the intensity of irradiation used by these authors was not great. (Compare below, page 356 and ²¹⁴).

Sodium stearate solutions have also been carefully investigated. Such solutions show considerable deviation from Poiseuille's law and an unusually great increase of viscosity with concentration. Freundlich and Gillings⁶⁹ found that the viscosity of these solutions is reduced rapidly by ultrasonics, provided the intensity exceeds a certain minimum value which rises with increasing concentration. The viscosity changes in this case are accompanied by a most marked change in appearance: whereas the original solution has a curdy, opaque, somewhat gelated, but generally homogeneous appearance, the irradiated solution is a limpid suspension of silky, needle-shaped, crystalline particles, showing streaks on stirring.

Ultrasonics seems in this case to accelerate a normally slow process somewhat

akin to crystallization. The collapse of cavities is essential to viscosity reduction.

Sound waves may, in the long run, be found to be a valuable tool for the investigation of the structure of many colloidal systems. An additional indication in this direction may be seen in the work of Brohult,³² who reports that the hemocyanin molecule is split into fragments of one-half and one-eighth the original value, if irradiated with ultrasonics. Confirmation and expansion of this highly interesting observation seems most desirable.

The denaturation of proteins has been reported many times.^{40, 41, 43, 128} In many cases it seems likely that there is a kind of surface denaturation. Further investigations would be desirable.

Accumulation and Orientation in Gaseous Systems. The best known ponderomotive effect of sound waves is the accumulation of fine solid particles in the nodes of a field of stationary sound waves in gaseous systems—Kundt's dust figures.^{122, 123}

With audible sound these figures are customarily demonstrated in the following manner (Fig. 8). One end (in Fig. 8, the left) of a horizontal glass tube is closed

FIGURE 8. Kundt's dust figures in gases.

by a movable air-tight piston. A glass rod, clamped at the middle, projects into the other end of the glass tube. A light-weight disc fitting the tube loosely is attached to the end of the rod within the tube. The rod is made to vibrate longitudinally by rubbing it. Its ends become antinodes; the disc at the end of the rod vibrates like a piston, thus imparting a regular succession of impulses to the air column enclosed in the tube. The piston on the other end of the tube is adjusted until at a certain position the node of the glass rod is considerably amplified. Now the air column is in resonance, its length being a simple multiple of the half wave length of sound in the gas, and stationary waves are set up. If some light, powdered material, *e.g.*, cork dust, is present in the tube, it collects in the nodes.

In the sound field generated by an ultrasonic vibrator the phenomenon is much the same; fine dust brought into the sound field collects in the nodes (see, *e.g.*,²²⁵). With high intensities the particles may even be kept suspended for a considerable time in the sound field, between the vibrator and a reflector.³⁴ (The coagulation resulting from this accumulation of particles will be discussed below.) The movements of the particles of an aerosol in a sound field are too complicated to be discussed quantitatively here. They have been considered by König;¹¹⁷ Brandt and Freund;^{25, 28, 29, 30} Brandt, Freund and Hiedemann;^{107, 109, 110} Lewis and Farris;¹²⁷ Wagenschein;²⁵⁴ and others.^{125, 132} We shall confine ourselves to a qualitative outline of this phase of sound physics.

The observed accumulation of the particles of an aerosol is the result of the slightly asymmetrical oscillations of the particles in the sound field. The individual particles of an aerosol follow the oscillations of the gaseous medium the more closely, (1) the lower the frequency, (2) the smaller the mass of the particle, (3) the lower its density, and (4) the higher the viscosity of the gaseous medium. Small, light particles follow the movements of the medium almost completely at low frequencies; at higher frequencies this movement decreases as the frequency increases. Large particles oscillate but little even at low frequencies, their inertia being great compared with the forces acting upon them; they are practically stationary at high frequencies. Brandt, Freund and Hiedemann¹¹⁰ have published photographs of particles of different diameters oscillating in a sound field. The images of the small particles are drawn out into streaks in the direction of the propagation of the sound waves, large particles appearing as stationary circles.

In the diagram of Fig. 9 are plotted the ratios of the amplitudes of particle and gaseous carrier, $\frac{A_p}{A_g}$, as a function of the particle radius, r , for four different frequencies, as calculated by Brandt, Freund and Hiedemann.¹¹⁰ These calculations refer to air of atmospheric pressure; the specific gravity of the particles is assumed to be 1. The curves of Fig. 9 are a quantitative expression of the above-mentioned general considerations for some special cases; they seem to be in satisfactory agreement with the observed facts. It is evident that with smoke and fog particles of the sizes that usually occur in natural and artificial smokes and fogs (1 to 5 μ), the strongest effects can be expected in the region of sonic and lower ultrasonic fre-

FIGURE 9. The ratio of the amplitudes $\frac{A_p}{A_g}$ in its dependence of particle radius for different frequencies.

quencies; with higher ultrasonic frequencies only the very smallest particles are still appreciably affected.

It is easy to visualize qualitatively that the impulses received by the oscillating particles toward a node and away from it are not strictly symmetrical. The impulses from the side of the loops are slightly larger, since the loops are the places of the maximum movement of the oscillating gas. The net result of this asymmetry of oscillation is that the particles are slowly shifted toward the nodes, where they accumulate. This accumulation leads to coagulation, and is therefore of interest to the colloid chemist.

Brandt, Freund and Hiedemann¹¹⁰ have also reported that non-spherical aerosol particles are oriented in a sound field. A detailed discussion of this problem is lacking.

Accumulation in Liquid Systems. As in gaseous systems, "dust figures" occur in liquids. If a sound wave travels through a liquid which contains dissolved gas, a part of the gas is driven out (see below) and unites in small bubbles; the gas bubbles accumulate in the nodal planes of stationary sound waves. This effect, first observed by Döring,⁶⁴ has been investigated carefully by Boyle and his collaborators^{15, 17, 18, 19}, etc. In progressing (not stationary) waves the bubbles are driven away from the source of sound. Similar effects can be observed with dispersed solids and liquids, as described by Boyle *et al.*^{16, 20} Particles settling in a liquid in which a field of stationary sound waves is set up accumulate in planes of half wave length and may, as they settle, be collected in beautiful stationary wave patterns on a horizontal plate.

Accumulation can be readily observed in all emulsions and suspensions.^{62, 133} Sollner and Bondy²¹⁹ have investigated accumulation more closely from the colloid chemist's point of view. Stationary wave patterns produced by ultrasonics in a liquid

were investigated in this manner: the emulsion (or suspension) is put into a thick-walled capillary slightly U-shaped in the middle; this part is dipped into the oil fountain of an ultrasonic generator, the two ends protruding horizontally sideways (Fig. 10). This arrangement avoids the very disturbing changes in concentration due to creaming up or settling down close to the meniscus. Stationary waves cause the formation of Kundt's dust figures (Figs. 10, 11a and b). With increasing time of irradiation the zones of accumulation become much sharper. Under favorable conditions thin discs with a well-defined boundary seem to stand upright in the liquid. The distance between two bands is $\lambda/2$, λ being the wave length in the liquid. With aqueous emulsions of benzene, toluene, etc., the first band is found at a distance of $\lambda/4$ from the meniscus (cf. Fig. 11a), *i.e.*, at a node, the meniscus always being the locus of an antinode. If exactly the same experiment is done with aqueous emulsions of nitrobenzene or mercury, or with a suspension of quartz, the first zone

FIGURE 10. Arrangement for the study of stationary wave patterns, about one-fourth actual size.

of accumulation lies at the meniscus itself, the next a distance of $\lambda/2$ from the meniscus, *i.e.*, at the antinodes (cf. Fig. 11b). So far as the experimental evidence goes at present, accumulation occurs at the nodes if the dispersed substance is less dense than the medium of dispersion, and at the antinodes if it is denser. However the decisive factor may not be simply the difference in specific gravity between the medium of dispersion and the disperse phase; it may be some closely related function which takes into account the different sound velocities. In an aqueous system containing particles both denser and less dense than water, ultrasonics may separate the two kinds of particles from each other. This is shown in Fig. 11c for a mixture of an emulsion of toluene and a suspension of quartz; this figure is evidently produced by a superposition of the effects shown in Fig. 11a and 11b. The zones of accumulation of toluene and of quartz alternate with each other, the distance between a band of the one and the other being $\lambda/4$. Toluene and quartz are readily distinguished by the fact that the former creams, whereas the latter settles. (The photographs 11a, b and c were taken from the side.)

The rate of accumulation of dispersed substances at the nodes or antinodes depends on the size of the particles, as is shown by the following experiments: three capillaries having the same dimensions were filled with suspensions of quartz (concentration about 3 per cent). The quartz powder had been roughly fractionated. The capillaries contained particles with diameters between 4 and 10 μ , 1 and 4 μ , and below 1 μ . On irradiation with medium energy, the wave patterns are formed immediately with quartz particles of 4 to 10 μ , the liquid between them being free

from particles. With the particles of 1 to 4 μ it takes a few seconds for the space between the striations to become practically free of particles, many seconds for the striations to become somewhat narrow, and a still longer time until the pattern is similar to that of the larger particles. With a suspension of particles of 1 μ and smaller, zones of diminished concentration appear after several seconds, and zones of a visible accumulation appear after a minute; but even after thirty minutes the whole pattern is blurred. In suspensions containing particles less than 0.5 μ the effect is still less distinct. In truly colloidal solutions accumulation has not been obtained at all by Sollner and Bondy with a frequency of 214,000 cycles per second.

FIGURE 11. Stationary wave patterns. (a) Toluene in water; (b) quartz in water; (c) toluene and quartz in water. About 1.5 times actual size.

The ponderomotive effects of sound waves were discussed by Boyle (see above) and King.^{114, 115} According to King the pressure on a sphere with a radius R in a sonic field of an energy E watt/cm² and a wave length λ is given by the expression

$$P = \pi R^2 \frac{(2\pi R)^4}{(\lambda)^5} E$$

The radiation pressure increases with the sixth power of the particle radius. Numerical evaluation¹⁰¹ shows that, in agreement with the observations of Sollner and Bondy,²¹⁹ no accumulation can be expected in truly colloidal solutions, whereas strong effects are predicted for emulsions and suspensions with microscopic particles.

The electrical effects which accompany the oscillations of colloidal particles in a sound field have been considered by Hermans^{98, 99} on the basis of earlier work on electrolytes by Debye.

A further quantitative study of the accumulation effect and its correlation to the mechanical properties of medium of dispersion and disperse phase, particle size and charge, etc., would be highly desirable; it is bound to yield much basic information from the point of view of the physicist as well as of the colloid chemist.

Orientation in Liquid Systems. On the basis of simple hydrodynamic considerations, Burger and Sollner²²¹ looked for and found a sonic orientation effect; anisometric particles are oriented in a sound field with their long axes perpendicular to the flux of energy. The phenomenon is best observed in a field of stationary waves. If a long test tube containing a dilute suspension of mica, mosaic gold, cer-

tain clays, or similar material is dipped into an oil bath containing a vibrating quartz oscillator, silky, brilliantly glittering zones at more or less regular half wave distance appear immediately, a sure sign of orientation; the term "sonic double refraction" has been suggested for this phenomenon. In suspensions with larger particles the orientation can readily be detected by close visual inspection. If the irradiation stops, orientation disappears immediately, except with rather large particles, in which case the orientation may persist for several seconds. The energy necessary to bring about orientation is very much smaller than that required for accumulation. Thus the two phenomena are very readily separated experimentally. This is easily understood, because in order to obtain any appreciable accumulation, particles must be moved several tenths of a millimeter, whereas orientation is effected by simply turning the particles into the favorable position, the maximum movement necessary being only of an order comparable with the length of the particles. Of course, the forces which bring about orientation are the same as those which (with higher energies) cause accumulation. Orientation is more pronounced in the antinodes than in the nodes, and larger particles are oriented much more readily than smaller ones. For example, in the experiments of Burger and Sollner three tubes containing quartz powder suspensions with particles from 4 to 10 μ diameter, 1 to 4 μ , and smaller than 1 μ respectively, were irradiated with medium energy. The 4 to 10 μ suspensions at once showed distinct glittering; subsequently the 1 to 4 μ suspensions followed, showing a weaker effect; finally came the finest suspension, the effect here being still weaker and not increasing, even after many seconds. It became distinct only when the energy was increased. Orientation (contrary to accumulation) can be observed with truly colloidal solutions, as was demonstrated with aged V_2O_5 and Fe_2O_3 sols; ²²¹ in concentrated sols the orientation can be detected in reflected light; in dilute sols transmitted polarized light is necessary. In very viscous, gel-like sols several minutes may be necessary to produce orientation; conversely the orientation may persist for many days after irradiation has ceased. Hermans,¹⁰⁰ Oka,^{155, 156} and Petralia¹⁶⁹ have investigated the orientation phenomenon further, and have tried to develop the physical theory of the effect, mainly on the basis of theoretical considerations of Pohlman¹⁷⁶ and King.¹¹⁵

Coagulation in Gaseous Systems. The coagulation of aerosols, *i.e.*, of fogs and smokes, is without doubt the most intensively investigated action of sound waves in colloidal or semi-colloidal systems. Sonic coagulation in aerosols has been discussed by Patterson and Cawood;¹⁶⁵ Brandt and Freund;^{26, 27} Pearson;¹⁶⁸ Andrade and Parker;^{2, 3, 163, 164} Gottschalk and Clair;⁸² Clair;^{48, 49} Dean;⁶⁰ Tatum;²⁴⁵ Gorbatschew;^{80, 81} Gies;⁷⁸ and others. It has been thoroughly investigated, particularly by Brandt, Freund and Hiedemann;^{24, 104, 105, 107, 108, 109, 110, 111} and reviewed jointly^{107, 109, 110} and separately by these authors.^{28, 104, 106}

It is well known that fogs and smokes coagulate spontaneously; practically all collisions between particles are non-elastic and lead to the formation of aggregates. The coagulation of aerosols can be greatly accelerated if they are exposed to sound waves. Photomicrographs of the sediments from fogs and smokes obtained with and without sonic treatment have been published by Brandt, Freund and Hiedemann.^{106, 108, 110} The untreated aerosols settled down as fine dust, mainly as primary particles; the sound-treated aerosols yielded sediments composed substantially of large aggregates.

The importance of the frequency of sound waves acting upon an aerosol was pointed out in a preceding section (see also Fig. 9); the strongest effects are obtained with higher audible and the lower inaudible frequencies. Most investigators, therefore, use magnetostrictive sound generators for work in aerosols in preference to piezoelectric generators. The gas-current vibration generator of Hartmann is also used frequently; Clair^{48, 49} has used an electromagnetic sound generator. (See pages 344 and 345.)

The usual experimental set-up consists substantially of a cylindrical gas chamber, either filled with the aerosol, or, more advantageously, through which the aerosol is allowed to flow continuously. For use with electrostriction sound generators, one end of this chamber is made of a pistol-like end-plate carried by the magnetostriction rod; the position of the other end-plate is adjustable, so that its distance from the vibrator plate is an integral number of half wave lengths. In this manner a stationary wave field may be set up, the intensity of which is many times that obtainable without this precaution. With air-jet sound generators, the Hartmann whistle is placed in the middle of a cylindrical gas chamber, provisions being made to adjust for resonance by means of adjustable end-plates.

Brandt and Freund²⁷ have followed the process of aggregation by means of microscopic measurements of the rate of sedimentation of the particles of aerosols. The results of such experiments are shown in Table 3. The aerosol contained in a cylindrical chamber was exposed to the sound action for five seconds. The frequency used was 10,000 cycles per second, produced by means of a magnetostriction oscillator. As the measure of the sound intensity the amplitude of the oscillations performed by the end-plate of the vibrator is given in the first column. In the second column is given the average observable rate of sedimentation of the particles; in the third, the calculated radius of the particles; and in the fourth, the ratio of the particle radii before and after irradiation. In the last column is the ratio of the masses of the particles before and after irradiation, as calculated from the rate of sedimentation.

Table 3. Coagulation of an Aerosol with Sound Waves²⁷

| Amplitude of the Vibrator (μ) | Rate of Sedimentation (mm/sec) | Average Radius of Particles (μ) | Ratio of Radii r/r_0 | Ratio of Masses m/m_0 |
|-------------------------------------|--------------------------------|---------------------------------------|------------------------|-------------------------|
| 0 | 0.5 | 1.8 | ... | ... |
| 9 | 0.77 | 2.3 | 1.28 | 2.1 |
| 18 | 1.8 | 3.7 | 2.06 | 8.7 |
| 36 | 2.5 | 4.3 | 2.4 | 13.6 |
| 54 | 16.7 | 10.5 | 5.85 | 200 |

In some cases aggregations to a mass several thousand times that of the primary particles have been observed. Brandt²⁴ has also studied these processes continuously by measurement of the light absorption. Fig. 12 shows the rate of aggregation expressed as m/m_0 for three different sound intensities, as before, in terms of the amplitude of the sonic vibrator. If the sonic treatment is carried out for any length of time, the aggregation leads to particles which are too big to be influenced by the sound field and which settle rapidly.

A quantitative theory of sonic coagulation is confronted with extraordinary difficulties, though the behavior of individual particles in a sound field is fairly well understood (see page 346 *et seq.*). In the process of coagulation, aerosols become very heterogeneous and the aggregates so formed deviate widely from a spherical shape. The worst difficulty is that the mechanism of coagulation is not simple, a number of not entirely independent factors working simultaneously to produce aggregation. The importance of these factors varies greatly with the particle size. At present one cannot do more than try to recognize the different possible causes for coagulation and to try to estimate their relative contribution to the observed effects. It is known that in aerosols nearly all collisions between particles are non-elastic and lead to coagulation. Therefore, all processes which increase the number of collisions between particles increase the rate of coagulation. The two main and primary factors are hydrodynamic attraction between the oscillating particles and the increased

probability of kinetic collisions between the particles oscillating with different amplitudes; the latter factor, as pointed out by Sollner,²¹¹ can be considered as a special case of orthokinetic coagulation (Wiegner;²⁵⁵ Müller;¹⁴⁸ and Tuorila²⁵⁰). In addition, there are the changes in concentration and the spontaneous sedimentation of the aggregated particles which leads to orthokinetic coagulation, as originally conceived by Wiegner and collaborators for liquid systems.

FIGURE 12. The rate of aggregation in an aerosol for three amplitudes of the sonic vibrator.

Let us first consider orthokinetic coagulation. In their work on suspensions Wiegner *et al*^{148, 250, 255} have distinguished between a "perikinetic" and an "orthokinetic" coagulation. Perikinetic coagulation is due to disoriented Brownian movement. In dilute aerosols it proceeds at a fairly low rate, much more slowly than sonic coagulation; it therefore can be neglected here. Orthokinetic coagulation, according to Wiegner and collaborators, occurs if a force, *e.g.*, gravity, acting upon the particles of the disperse phase makes them move with differing velocities according to their sizes. This causes collisions between particles of different size (in excess of those caused by Brownian movement) which lead to "orthokinetic" coagulation. Since aerosols are never homodisperse but always contain particles of various sizes, a sound field imparts different velocities to different particles (see Fig. 9); this leads to additional ("orthokinetic") collisions and in turn to orthokinetic coagulation. Brandt, Freund and Hiedemann^{104, 109, 110} have tried to estimate the orthokinetic fraction of the observed coagulation in a sound field. They based their calculation on the assumption that there are two kinds of particles in the aerosols: large ones which do not oscillate at all and small ones which oscillate with the same amplitude as that of the medium. Thus, each large particle can be considered to be surrounded by a zone of aggregation, the magnitude of which depends on the oscillations of the small particles. On the basis of these considerations the above-mentioned authors conclude that with suitable frequencies and in fairly concentrated aerosols, orthokinetic coagulation is a sizable fraction of the observed effect.

The problem of sonic coagulation becomes still more complex if we turn to the forces of attraction which originate between two oscillating particles. The most important among these forces is hydrodynamic attraction, as discussed by Bjerknes¹¹ and König.^{117, 118} Further, there are vortex formation, the pulsation of liquid par-

ticles, etc., which seem to play only minor roles however. König has calculated the force of attraction between two oscillating particles. It is believed to be proportional to the third power of the particle radii and inversely proportional to the fourth power of the distance between the two particles. Brandt, Freund and Hiedemann^{109, 110, see also 48, 49, etc.} have tried to use these calculations to estimate the rate at which the two spheres approach each other. However, it seems a practical impossibility to apply such calculations with any degree of accuracy to aerosols, for it would be necessary to consider not two, but numerous particles influencing one another over different distances, which vary with time. The whole problem is further complicated by the fact that particles which approach each other through the forces which cause orthokinetic coagulation are brought into positions which are favorable to hydrodynamic attraction; thus, the two different processes are linked together and accelerate the coagulation. Brandt, Freund and Hiedemann, in view of the tentative nature of all these considerations, have confined themselves to rather qualitative estimates, and conclude that, in the range of sonic and lower ultrasonic frequencies, hydrodynamic attraction cannot account for the observed rate of coagulation without assuming orthokinetic coagulation to occur as well. In spite of much thorough work this is about the present state of our knowledge of sonic coagulation—a rather unsatisfactory one from the physicist's point of view.

Numerous attempts have been made to apply sonic coagulation methods to the precipitation of industrial fogs and smokes. Since coagulation occurs readily in streaming aerosols it is possible to handle large volumes; however, no definite statement can be made at present as to whether or not sonic coagulation may be developed into an industrial method; the chances that this may be achieved seem to be rather good.

Coagulation in Liquid Systems. The coagulating action of sound waves in emulsions and suspensions containing macroscopic particles on the one hand, and truly colloidal solutions on the other, seems to be due to entirely different mechanisms; the two cases must therefore be treated separately.

The coagulation of systems containing visible particles has been reported repeatedly by Dörsing,⁶⁴ by Boyle and collaborators,^{16, etc.} by Wood and Loomis,²⁵⁶ and others. These authors attribute the phenomenon to radiation pressure. Coagulation in liquid systems was investigated later by Sollner and Bondy²¹⁹ on a qualitative basis from the colloid chemist's point of view. A quantitative study accompanied by a thorough theoretical treatment of the problem, though highly desirable, is still missing.

The coagulation of systems with microscopic particles can be demonstrated very strikingly by irradiating an unstable suspension, *e.g.*, quartz powder in an organic liquid. If a test tube containing such a suspension is irradiated even with low sound intensities, the particles accumulate and aggregate; the aggregates so formed soon reach a size which favors rapid sedimentation. A few seconds of weak irradiation are sufficient to clear suspended particles from the liquid almost completely. The coagulation and coalescence of gas bubbles developed in a saturated, or better, in a supersaturated solution of gas in a liquid is also striking. If such a supersaturated solution of gas is irradiated with sound waves for a few seconds, it turns milky white a few seconds later; innumerable small gas bubbles are formed (see page 349). A further brief irradiation causes the gas bubbles to coalesce and to accumulate in more or less regular stationary wave patterns. Soon the gas bubbles become so large that they can no longer be held at these points by the sound waves and rise to the surface.

In a less spectacular manner the same result is also obtained with more stable systems. The concentration of a mercury emulsion (in the absence of a bulk mercury phase), for example, was reduced from about 6 to less than 1 g per liter by 30 seconds of fairly strong irradiation. The absence of a bulk mercury phase is neces-

sary to study the phenomenon of coagulation without interference by simultaneous emulsification. As pointed out in a previous section, in the presence of a mercury macro-phase a stationary concentration of disperse phase is soon reached on irradiation: emulsification and coagulation balance each other.

In the case of the coagulation of mercury emulsions one actually observes not only the aggregation of the original particles, but also their coalescence into larger mercury drops.

Coagulation quite visibly occurs in the zones of accumulation in the liquid. These zones become more pronounced and more regular if higher columns of the emulsion are used in long test tubes. This explains why the concentration of dis-

FIGURE 13. Coagulation of an emulsion by ultrasonics, about one-third actual size.

persed mercury, which can be obtained by sound treatment, depends greatly on the volume of the aqueous phase; for, in a given test tube and with a given quantity of bulk mercury the amount of mercury dispersed per second at a given intensity of irradiation is independent of the size of the water phase; on the other hand, the rate of coagulation in the water phase as a whole increases with its volume.

With oil emulsions the situation is very similar. Cavitation, however, becomes a disturbing factor unless very low sound intensities are used or unless it is prevented by pressure. A toluene-in-water emulsion after a few minutes of moderately strong irradiation (without the prevention of cavitation) is shown in Fig. 13. Accumulation, coagulation and coalescence occur rapidly in the middle and lower part of the test tube; the three phenomena may be observed readily under a microscope.²¹⁹ Near the surface, where cavitation and thus emulsification is favored, the milky appearance of the emulsion persists; a stationary state between emulsification and coagulation, which is different for different layers (see Fig. 13), is soon reached.

Thus with proper precautions emulsions may be broken readily. It is obvious that the shape and size of the vessel in which emulsification and coagulation occur simultaneously must necessarily play an important role in determining the ultimate concentration of the emulsion obtainable. By prolonged application of sound intensities too weak to cause emulsification, emulsions may be broken completely. Under favorable conditions this is true also for many stabilized emulsions.

With highly protected emulsions the particles aggregate, but little coalescence occurs; the aggregates may be dispersed easily by little stirring after irradiation stops. The same, of course, is true for highly charged, stable suspensions.

Qualitatively, Sollner and Bondy²¹⁹ explain the coagulating action of sound waves in systems with microscopic particles in this manner: first, the particles are accumulated and the rate of spontaneous coagulation increases rapidly as the concentration increases; secondly, particles of different size migrate with different velocities toward the zones of accumulation, thus being liable to additional collisions, a kind of "orthokinetic" coagulation;^{148, 250, 255} thirdly, the particles do not migrate only in one direction; their macroscopic movements is merely the result of the asymmetry of the oscillations which they perform according to their (different) size; this too causes a kind of orthokinetic coagulation. Whether the factors enumerated are a sufficient and complete explanation of the phenomenon is still open to question; it is not impossible that hydrodynamic attraction between oscillating bodies (*e.g.*,¹⁶¹) in the zones of accumulation come into play; dipole forces which are believed¹⁰¹ to be the most important single factor with truly colloidal solutions should possibly be considered also in the case of macroscopic particles.

The coalescence of the particles of poorly stabilized emulsions, which is observed as soon as coagulation sets in, does not need further discussion; this process, occurring at a slow rate in the absence of sound waves, is greatly enhanced by the ponderomotive action which brings the particles into close contact. It seems not improbable that sonic coagulation of suspensions and emulsions (crude oil) may assume technical importance in the future.

In truly colloidal solutions coagulation may also be brought about by sound action. The mechanisms involved, however, must of necessity be of a different nature, since the ponderomotive effects responsible for the coagulation in systems with microscopic particles are practically absent, as pointed out on page 359. Boutaric and Bouchard¹³ observed that the rate of coagulation of unstable sols of gum mastic and A_2S_3 may be increased by ultrasonic irradiation, if the latter causes a gross stirring. If, however, the system was arranged to prevent gross stirring and only a field of stationary waves was set up, no acceleration of the rate of coagulation was observed. Thus no specific sound action on the rate of coagulation was observed by Boutaric and Bouchard; the effect of gross stirring is not specific, being well known under the name of "mechanical coagulation" (see also²⁰⁹). Hermans has investigated the problem further theoretically,^{98, 99, 102} as well as experimentally,¹⁰¹ with dilute ($0.3 - 3 \cdot 10^{-3}$ mol/l) AgI sols containing a 50 per cent excess of KI. The resulting bluish-green sols were reasonably stable, and in the lower range of the concentrations used were perfectly clear. Their coagulation rates were studied tyndallometrically.

The very slow rate of spontaneous coagulation in the original sols is hardly influenced by sound treatment. In the presence of electrolytes NH_4Cl , $NaNO_3$, KNO_3 ($0.6 - 0.24$ mol/l) and $BaCl_2$ ($0.001 - 0.02$ mol/l) the rate of coagulation is increased in a sound field of moderate or high energy. This influence is very pronounced at low electrolyte concentrations, that is in the range of "slow coagulation," while it becomes almost negligible at high electrolyte concentrations, where the coagulation is rapid. In the case of $BaCl_2$, the effect is less pronounced than with the uni-univalent electrolytes. In a sol protected with starch no influence of a sound field was observed. Hermans thinks that the turbulent motions and convection

currents observed in his systems upon irradiation are of no consequence. He goes on to show that cavitation does not cause the increase in the rate of coagulation; nor do heat effects, the kinetic energy of oscillations, orthokinetic coagulation, accumulation, or hydrodynamic interaction between the particles, according to Hermans, offer a satisfactory explanation. The most promising explanation at present is seen in the dipolar interaction of the oscillating particles ("migrating dipoles") which results from the distortion of the electric double layer. The basic consideration in this concept is this: as soon as a particle acquires a velocity with respect to the solvent, its electric double layer loses its spherical symmetry, and a dipole is set up.^{98, 99} These dipoles are all lying in the same direction, namely, that in which the sound is propagated. The dipole forces between two particles which follow each other in the same line are attractive, and result in an increased rate of coagulation.

The problem of sound coagulation in truly colloidal solutions still seems to be far from a definite solution; much more experimental work with a variety of solutions is needed.

Influence of Sound Waves in Rheoplectic and Dilatant Systems. *Rheopexy.* The time of solidification of certain types of thixotropic systems is shortened by submitting them to a more or less regular movement, such as tapping the test tube containing the sol or slowly rolling it to and fro between the palms of the hands. This phenomenon was called rheopexy.⁷² Rheoplectic solidification seems to have a relationship to coagulation produced by stirring. Rheopexy is found with any suitable disperse phase only in narrow ranges of concentration and electrolyte content. Rheopexy in sound fields was found by Juliusburger and Pirquet¹¹² and studied by Burger and Sollner.²²¹

A kaolin with particles mostly below 1 μ gave a thixotropic and rheoplectic suspension if mixed with 1.6 ml 2N NaCl per g kaolin. The spontaneous (thixotropic) solidification time was 17 minutes. Upon tapping, this suspension solidified after 30 seconds; in an ultrasonic field of moderate energy only 15 seconds were required for solidification. When it was irradiated for a longer time, zones of accumulation were gradually formed in the paste. Similar results were obtained with gypsum which, like kaolin, has anisometric particles which may be oriented by sound waves.

The particles of Solnhofen slate are approximately cubical; they do not show an orientation effect. However, rapid solidification can be obtained by weak ultrasonic treatment. Therefore, in this case at least, rheopexy is possible without orientation, the accumulation of the discharged particles probably being the only cause of their becoming a paste.

Plastic clay, as used for molding purposes, shows rheopexy when in suitable concentrations, upon tapping the test tube containing the sample or rolling it to and fro. Its particles are anisometric, for dilute suspensions show the orientation phenomenon. It was, however, impossible to detect a shortening of the time of solidification in a sound field under the various conditions of concentration and electrolyte present. The tendency to form stiff gels—as distinct from the rather soft pastes of kaolin and Solnhofen slate—is apparently also the reason that rheoplectic solidification with ultrasonics cannot be observed. The individual particles are bound so firmly to one another that the sound waves are unable to move and rearrange them. Zones of accumulation have never been observed in concentrated systems of this kind.

Rheoplectic solidification due to ultrasonics has so far not been observed in V_2O_5 sols (containing suitable electrolytes), which otherwise show pronounced rheopexy. The interaction between the particles of these very viscous gel-like V_2O_5 systems is obviously so strong that even orientation by sound waves is rendered impossible.

Generally speaking, a solidifying influence of ultrasonic radiation is to be expected in those rheoplectic systems which are more paste- than gel-like, and whose

particles are big enough to be influenced—by being either oriented or moved—individually by the sound waves.²²¹

Dilatancy. If the supernatant liquid is poured off the sediments of suspensions, such as quartz powder or sea-sand, the sediments are somewhat moist and soft, when only a slight pressure is applied. However, as soon as a stronger, one-sided, pressure is applied, a sediment of this kind becomes dry and hard and offers considerable resistance to a penetrating instrument; as soon as the pressure ceases, the whole mass usually becomes moist again. This phenomenon, called dilatancy, was explained by Osborne Reynolds¹⁸⁴ in the following way: in moist sand the particles tend to become very closely packed. If an external force displaces the particles, the packing becomes looser and consequently water is sucked in, thus leaving the sediment apparently dry and hard. While a system normally exhibiting dilatancy is exposed to ultrasonics it is possible to drive an instrument through the sand to the bottom of the vessel without much resistance. Other experiments show that the sand under the influence of the ultrasonic radiation is more closely packed than after being left undisturbed for quite a long time, or after being tapped frequently to promote settling.

It seems to hold true generally that dilatant and, therefore, non-plastic systems can be rendered somewhat plastic for the duration of intense sound treatment.

It can readily be shown that cavitation is not connected with the influence of ultrasonics on dilatancy; quite obviously the effect of sound waves on dilatancy is due to the ponderomotive action of the sound waves. The particles when oscillating and moving under the influence of sound waves do not stick to each other, but may move relatively freely over one another as an instrument penetrates the sediment.

Degassing of Liquids. If a sound wave travels through a liquid which is saturated with gas, a part of the gas is driven out and unites in small bubbles, as first described by Dörsing.⁶⁴ What happens to these gas bubbles once they are formed was discussed above (page 348). The degassing effect has been studied carefully by Boyle and collaborators.^{14, 15, 16, 17, 18, 19, 21, 22} Boyle is inclined to see the explanation of the phenomenon in the coalescence of minute gas bubbles mainly adhering to dust particles which are supposed to be always present in a liquid. These gas bubbles coalesce on sonic irradiation and thus become visible. The bubbles originally present or enlarged by coalescence obviously could grow when the liquid is stretched locally by a sound wave travelling through it. Boyle does not think that this stretching of the liquid alone could account for the appearance of gas bubbles. It seems to the author that the true explanation should emphasize these considerations. If a sound wave passes through a liquid which is saturated with gas, the liquid is stretched periodically, and in this period it is supersaturated with respect to the gas. The assumption of the universal presence of minute (and therefore unstable) gas bubbles seems most unlikely and is not supported by other evidence. This is another phenomenon which needs careful reinvestigation.^{see 166, 224} In many experiments, particularly those involving stationary wave patterns and related phenomena, the occurrence of degassing is a rather disturbing factor; this difficulty can be overcome by working with partially degassed liquids, or by the application of a small outside pressure on the liquid.

The degassing of liquid and fused masses like melted metals and glass was suggested by Krüger¹²¹ and others.^{116, etc.} In these cases, however, the degassing may easily be more an accumulation and coagulation of preformed gas bubbles than a primary true degassing. That this may occur even in very viscous systems was shown early by Freundlich, Rogowski and Sollner⁷⁶ in the case of very viscous technical viscose solutions. The degassing of glass, etc., may easily assume practical importance in the future.

Thermal Effects of Sound. Intense sound treatment in liquid and solid systems is always accompanied by considerable thermal effects which are very greatly increased

in the presence of extended phase boundaries, as they occur in micro-heterogeneous systems.

In pure liquids and in homogeneous solutions the thermal effect is due to the absorption of sound energy which is intimately connected to the viscosity of the liquid. Wood and Loomis²⁵⁶ point out that the kinematic coefficient of viscosity increases as the square of the frequency. Thus sound absorption is very pronounced at medium-high ultrasonic frequencies (about 200,000 cycles per second); temperature increases in irradiated liquid samples of up to 1° C in three seconds have been reported by Wood and Loomis; 5 to 10° C temperature rises are common and usually unavoidable when studying emulsification, etc. Frequencies of 500,000, and more so of 1,000,000 cycles per second, are so strongly absorbed that their propagation through the irradiated systems is very limited. This is one of the main reasons why these higher frequencies have not been used to any extent for colloid work, for which high intensities are ordinarily required. A good discussion of the problem of heat evolution was given by Richards.¹⁸⁷ Measurements with different substances have been reported, *e.g.*, by Dognon and Biancani.⁶²

It is well known that the propagation of sound is much poorer in a liquid containing gas bubbles than in their absence; vibrational energy is dissipated and transformed into heat. Emulsions and suspensions heat up rapidly if irradiated, many times faster than do the corresponding homogeneous macro-phases. The importance of interfaces in the heating effect has been very clearly demonstrated for the case of solids by Wood and Loomis. A block of newly formed ice (distilled water frozen in a beaker by ice and salt) was subjected for two minutes to the action of intense sound waves in a beaker of ice water containing numerous small fragments of ice which kept the temperature of the water at 0° C. At the end of the sonic treatment, the block of ice, on being squeezed between the fingers, broke up into small fragments, showing that liquefaction had taken place throughout the mass of the ice. With natural ice (pond ice) this experiment could not be duplicated. Wood and Loomis ascribed this to the fact that in the latter case one was dealing with a single crystal, whereas in the case of artificial ice we have a mass of interlocking crystals, the heating taking place at the crystal interfaces.

Some early observations on heterogeneous systems were reported by Freundlich, Rogowski and Sollner,⁷⁶ who found with macroscopic objects (glass beads, lead shot) in water an increasing heat effect with decrease in size. In heterogeneous systems the heat effect is due to a number of factors, the relative importance of which depends on the system under consideration. There is first the absorption of sound in the medium of dispersion and the disperse phase; gross stirring, the irregular reflection and the scattering of sound on the interfaces medium of dispersion—disperse phase; the friction between the particles and the oscillating dispersion medium. From the discussion on pages 357 to 359, it is easy to see how the last-mentioned factors must depend very strongly on the particle size; systems with very small particles, as true solutions, scatter but little energy, the solution acts as a homogeneous medium. With macroscopic particles only a limited area of interfaces can be accommodated in a given volume. One may assume that maximum heat effects with medium-high ultrasonic frequencies are obtained in systems with microscopic particles.

There is one additional factor not mentioned so far, which under the conditions of colloid work frequently comes into play: cavitation. The formation of cavities consumes considerable energy which finally appears as heat, and the cavities, as long as they exist, prevent the smooth flow of sound energy by reflection and scattering. A detailed investigation of the heat effect in heterogeneous systems has never been carried out, for such a study does not seem to promise results of great or general interest which could not be obtained more easily in another way. (Compare also¹⁸⁸.)

The generation of heat is actually a disturbing factor in many investigations with sound waves, particularly in the range of ultrasonic frequencies. Cooling is only a partial remedy; by cooling, the average temperature of an irradiated system may be kept within reasonable limits; the local effects at the phase boundaries, however, cannot be suppressed. There is little doubt that this local increase in temperature accelerates many dispersing actions of sound waves. How intense this local heating may be was demonstrated early by Freundlich, Rogowski and Sollner,⁷⁶ who irradiated crystals of gallium in water with strong ultrasonic waves; a concentrated suspension of gallium was obtained, though the crystals were not liquefied by the heating of the system, but kept their shape. Close inspection showed that the crystals were melted at their surfaces; this indicates that the gallium was actually dispersed in the liquid state, being first locally liquefied by the action of the sound waves. Many similar observations can be found in the literature.

The fact that considerable heat development cannot be prevented in many phases of colloid work is one of the drawbacks of the application of sound methods in this field.

It has been suggested^{75, etc.} that one might utilize ultrasonic radiation for medical purposes, such as the heating of joints, the marrow inside intact bones, etc.

Chemical Effects, Crystallization, etc. A discussion of the chemical action of sound waves is, strictly speaking, outside the framework of this review and can be referred to only briefly. The chemical effects can be classified arbitrarily into: (a) oxidation reactions which are usually accompanied by some light effects; (b) depolymerization which was discussed on pages 354 to 366; (c) the destruction of labile states, the influencing of crystallization, the acceleration of reactions; (d) electrochemical actions, such as the neutralization of passivity.

Oxidation. Schmitt, Johnson and Olson²⁴² first showed that strong ultrasonic irradiation of water containing oxygen leads to the formation of H_2O_2 . This, as established later, is due to the activation of oxygen by the collapse of cavities. In the presence of suitable reagents the activated oxygen, of course, may bring about many varied oxidation reactions. The activation of oxygen is accompanied by the emission of light (sonoluminescence). The problem of sonic oxidation and sonoluminescence was reviewed by Newton Harvey,⁹² to which review the reader is referred. (For further references see: 10, 31, 36, 39, 45, 66, 67, 68, 79, 126, 129, 130, 157, 167, 177, 222, 242.) The influence of ultrasonic irradiation of the photographic plate (increase of blackening, occurrence of stationary wave patterns, etc.) is probably due mainly to oxidation.^{134, 137, 138, 141, etc.} The oxidation effect may also play some role in the case of the improved photographic emulsions reported by Claus and collaborators (see page 352). Whether or not oxidation reactions play a role in the depolymerization of high polymers is not known. (For the acceleration of hydrolysis etc. see^{197, 243, 251}.)

Labile states may frequently be changed to more stable ones. Such effects as the sudden boiling of superheated liquids²⁵⁶ or the detonation of highly sensitive explosives when subjected to sound waves^{12, 136, 256} do not require further comment.

Of greater interest here is the spontaneous crystallization from supersaturated solutions which frequently occurs; its mechanism is unknown. (See 1, 5, 8, 58, 59, 204, 210, 256.) This effect has considerable metallurgical interest.^{35, 65, 202, 208, 237, 238, 239} The crystalline structure of metals and alloys is changed by sonic treatment during solidification; the grain size is generally reduced and the growth of dendrites sometimes favored; however, the results of different authors vary widely, probably due to the difference in the systems investigated and the different sound frequencies used.

Masing and Ritzau,¹⁴² and Schmid and Ehert²³⁷ have prepared dispersions of one immiscible metal in another (Pb in Al, Ca in Si, etc.), by the application of intense sound waves. The mechanism causing these dispersions is unknown.

It seems possible that sonic methods may soon find practical application in attempts to improve the properties of metals and alloys.

Electrochemical effect. A number of electrochemical actions of sound waves have been reported, foremost among them the neutralization of passivity by sonic treatment, and changes in electrode potentials. The neutralization of passivity finds its obvious explanation in the destruction of protecting layers, undoubtedly due to cavitation. If the protecting layers are sufficiently damaged, the electrode potential changes rather abruptly to the reversible value. For further observations and discussion we must refer to the literature.^{145, 146, 150, 151, 152, 153, 174, 175, 231, 232, 235, 236, 237, 257}

Biological Effects. A discussion of the biological effects of sound is still further from the central theme of this review than are the chemical effects sketched in the preceding section; a few general remarks must suffice here. If one considers the different disruptive and destructive, ponderomotive, and chemical actions of intense sound waves discussed, it is small wonder that living systems too may be affected greatly by intense sound treatment. Intense irradiation may lead to a destruction of the organized cell structure and even to complete disintegration, as first shown by Wood and Loomis.²⁵⁶ A very great number of observations have been reported; at present, however, an attempt to coördinate this material may be premature. Somewhat arbitrarily the reader is referred to the work of Harvey and collaborators,^{90, 91, 94, 95, 96, 97} and Chambers and collaborators^{38, 42, 44, 47, 93} etc. The reviews of Dognon and Biancani,^{62, 63} Harvey⁹¹ and the fairly recent one by Hiedemann¹⁰⁶ give a useful picture of the application of high-intensity sound waves to biology.

Acknowledgments

The author wishes to thank Dr. E. S. Fetcher, Jr. and Dr. M. B. Visscher for reading the manuscript; the editor of the *Transactions of the Faraday Society* for permission to use freely his papers published therein and to reproduce a number of photographs; the editor of the *Journal of Physical Chemistry* for reproducing some figures; the editor of the *Journal of Dairy Science* for permission to quote verbatim an article by Dr. L. A. Chambers and to reproduce Fig. 4; and the editors of the *Proceedings of the Society for Experimental Biology and Medicine* and Dr. L. A. Chambers for the permission to reproduce Fig. 3. Acknowledgment is also made for a verbatim quotation from a paper by H. W. St. Clair, presented at the dedication of Bureau of Mines Experiment Station, Salt Lake City, Utah.

The Cyclotron and Some of Its Uses *

JEROME ALEXANDER

Many important advances in science and technology radiate from the discovery of new facts, new apparatus and new methods which, though at first laboratory curiosities, may later enter wide use in the home, hospital or factory. It is only a

* This paper was assembled by the Editor mainly from publications of Professors Ernest O. Lawrence, John H. Lawrence, and Joseph G. Hamilton, of the Crocker Radiation Laboratory, University of California, Berkeley, Cal., who have also kindly consented to check over the manuscript. Figure 1 is reproduced from *Electrical Engineering*, July, 1942, and the remaining illustrations are from cuts kindly supplied by Rutgers University Press from "Molecular Films, The Cyclotron and the New Biology" (1942) by Hugh Stott Taylor, Ernest O. Lawrence and Irving Langmuir. The Editor expresses sincere thanks for this coöperation.

few years now since mechanical refrigeration, founded on the experiments of physicists, supplanted the iceman in so many homes; and out of the "Edison effect" of leaking electrons there developed the radio tube.

The cyclotron, which already means much in physical, biological and medical research, is a magnetic resonance accelerator in which ionized particles are given successive impulses of acceleration by charged electrodes, while being constrained to follow a circular path in a powerful magnetic field.

According to a theorem originally due to Larmor, the angular velocity of a charged particle in a magnetic field is independent of its linear velocity. Figure 1

FIGURE 1. Schematic diagram of the cyclotron.

gives a schematic diagram of the cyclotron, above in section, below in elevation. The D-shaped hollow accelerating electrodes (called "dees") are maintained in a hydrogen vacuum (pressure of about 10^{-4} mm of mercury), and are activated by an alternating voltage applied across the electrodes by an oscillator at a frequency of the order of 10 megacycles. Consider the behavior of a single positive ion, liberated, for example, by a heated tungsten filament between the dees. The ion will be attracted toward whichever dee happens to be negatively charged at the moment, and entering the hollow of the electrode (where it is free from electrostatic attractions) follows a semi-circular path in the magnetic field until it reaches the gap between the dees. There it encounters the attractive force of the opposite dee (for the oscillation speed is suitably synchronized) and enters the hollow of this dee with a further increase in velocity. With each passage across the electrode gap, the ion is thus given a new increment of acceleration and follows an ever-widening circle, until near the periphery of one of the dees, where there is a window in a jog, it passes out of the hollow electrode under the pull of a deflecting electrode and strikes a target with tremendous velocity.

Assuming an alternating current of 50 kv across the dees, after 50 revolutions (100 gap crossings) an ion of unitary charge (a proton, ${}_1\text{H}^1$, or a deuteron, ${}_1\text{H}^2$) would have an energy of five million electron-volts. Under like conditions an alpha particle (helium nucleus, ${}_2\text{He}^4$) because of its double charge, would acquire twice this energy. The 60-inch cyclotron at the University of California (Berkeley, Cal.), the largest now in operation, gives a deuterium ("heavy hydrogen") beam with an energy of 16 million electron-volts, which produces a lavender luminosity in air for a distance of 4.5 feet after emerging from a special window or a vacuum gate. The 100 million electron-volt cyclotron, now under construction at Berkeley, is expected to give a beam 140 feet long in air.

"The beam in air looks rather pretty, but its appearance hardly suggests its latent powers. However, some conception of the energy in the beam is gained when a steel plate is placed in the path of the beam, for it is immediately melted and cut through. . . . A much more subtle danger, moreover, lurks in it because, as the swiftly moving particles lose their energy, they make nuclear collisions giving rise to penetrating nuclear radiations—the gamma rays and neutron rays, which like x-rays produce harmful and even lethal effects in excessive doses. It is for this reason that the cyclotron is so carefully surrounded by large masses of absorbing material to protect the operators." ¹⁷ (Figure 2).

FIGURE 2. The 16 million electron-volt deuteron beam emerging from the cyclotron chamber into the air. An indication of its size may be gained from noting the meter stick placed below the beam.

In 1919 Ernest Rutherford (later Lord Rutherford) demonstrated the first laboratory transmutation by showing that particles (helium nuclei) emitted with energies of 5 to 10 mv by naturally radioactive elements (radium "C," polonium) could, upon collision with the nucleus of a nitrogen atom, cause the ejection of a proton. About five years later P. M. S. Blackett was able to take photographs which indicated that the helium nucleus (${}_2\text{He}^4$) was captured by the nucleus of the main nitrogen isotope (${}_7\text{N}^{14}$), forming an unstable grouping which immediately split into two particles, one a proton, the other having a mass of 17. Assuming the now well recognized conservation of charge this change may be thus indicated:

It was later discovered that while 99.76 per cent of oxygen atoms have a mass number (M) of 18, there are two oxygen isotopes, 0.04 per cent with M = 17, and 0.20 per cent with M = 18.

The "natural" particle projectiles were able to produce transmutations in many among the first score of elements in the periodic table, but the heavier elements resisted change. Scientific advance demanded projectiles of increased energy with which to bombard the resistant atomic nuclei, and Cockcroft and Walton (Cam-

bridge) developed a circuit whereby a pulsating voltage of about 700 kv could be applied to a discharge tube so that the tube could deliver protons having this maximum energy. Lauritsen, of the California Institute of Technology, produced particles having a million volts by using cascaded transformers. Van de Graaff (Massachusetts Institute of Technology) constructed very high voltage electrostatic generators. The tremendous difficulties of handling these high voltages and of constructing tubes to withstand them were cleverly avoided by the cyclotron of Lawrence and Livingston (University of California^{1, 3, 12}) which accelerates a particle not once but many times, to produce projectiles having energy sufficient to crash into the nucleus of any atom.

The present uses of the cyclotron stem from the fact that its potent beam is able to produce nuclear changes in all the 92 elements, resulting in transmutation of the atoms into new elemental or isotopic forms. In most cases there are produced unstable nuclei having various periods of half-life, which are radioactive and, on their course to stability, emit subnuclear particles (*e.g.*, neutrons, electrons, positive electrons) as well as intense γ radiation.

If the target of the cyclotron contains beryllium atoms and the projectiles are deuterons (heavy hydrogen nuclei) a very unstable radioactive isotope of boron is formed, which immediately breaks down, liberating *neutrons* with an energy of 21 million electron-volts. Since neutrons are without any net charge, they possess profound penetrating ability, like x-rays, whereas charged particles, *e.g.*, protons, are stopped by a few millimeters of solid material. Energetic neutrons are being widely applied in the medical and biological fields, to treat cancer* and to produce chromosomal changes. Figure 3 shows schematically the liberation of high-energy neutrons.

FIGURE 3. The nuclear reaction which is graphically represented here indicates the mode in which the bombardment of beryllium atoms by deuterons results in the release of energetic neutrons.

The potent local effect produced by a neutron beam is shown in Figure 4, which illustrates the intense ionization produced in a Wilson cloud chamber containing air, hydrogen and water vapor. The thick-appearing, dense tracks were produced by recoil protons resulting from collisions of neutrons with hydrogen nuclei; the thin tracks arise from secondary electrons liberated by gamma-rays. Incidentally, although these tracks appear more or less continuous, they really consist of colloidal or near-colloidal water droplets which form about ionized particles when the moving piston causes sudden expansion and chilling of the moist air within the chamber.

The pioneer experiments of G. Hevesy,⁹ who employed radium D (a radioactive

* See Podolsky, "The War on Cancer," Reinhold Publishing Corp., 1943.

isotope of lead) to investigate lead metabolism in plants, were abortive because lead as well as bismuth, which was later tried (radium E is radio-bismuth), are not normal plant constituents. Hevesy was able to measure quantitatively the uptake and distribution of the lead by determining the radioactivity of various parts of the plant; for this method is over a million times more sensitive than ordinary chemical or physical analysis, and the traces of metal used were far below the threshold of toxicity.

The discovery of artificial radioactivity by I. Curie and F. Joliot⁵ made available radio-nitrogen, radio-silicon, and radio-magnesium; but the discovery of the cyclotron by E. O. Lawrence quickly led to the production of a great number (to date, about 350) of radio-isotopes and radio-elements,* some of which are important

FIGURE 4. Ionization produced in a Wilson cloud chamber filled with a mixture of air, hydrogen and water vapor after bombardment with neutron rays and gamma-rays from the cyclotron. The thin tracks of ions were produced by secondary electrons liberated by the gamma-rays, while the thick and very dense tracks were produced by the recoil protons resulting from collisions of neutrons with the hydrogen atomic nuclei. This picture demonstrates the more localized and intense ionization produced in tissues by neutrons when compared with X-rays or gamma-rays.

normal constituents of plants and animals, can be produced in "quantity," and have a sufficiently long "life" to make them experimentally valuable, *e.g.*, phosphorus, sodium, iodine, calcium, carbon, and nitrogen. The cyclotron can also produce usable quantities of the rare "triple hydrogen," *tritium*, which has a half-life of about 10-15 years, and can be readily stored and handled by being combined with lithium as the "hydride," lithium tritide (LiT).

Three techniques have been developed to apply the radio-isotopes to medical and biological problems:

- (1) Administration of a suitable chemical compound, followed by measurement, with an electroscope or a Geiger counter, of the radiation from each individual tissue.
- (2) Autoradiography, first devised by Lacassagne and Lattes,¹¹ which involves placing portions of the biological material, for suitable periods, within effective range of photographic plates, which on development indicate the loci where radio-elements are fixed.^{8, 14, 15}
- (3) The *in vivo* technique, developed mainly by J. G. Hamilton, involving the study of the absorption, distribution, and deposition of the various radio-elements in the intact organism, by placing the Geiger counter over the part to be studied, *e.g.*, over the thyroid with radio-iodine.

Investigations with radio-phosphorus, which emits beta rays having a penetration of less than a centimeter in tissue, showed that it was localized mainly in bone marrow and bone. This led J. H. Lawrence to experiment on mice suffering from leukemia. He found that wherever there is leukemic infiltration there is a high phosphorus uptake.¹³ Leukemic tumor (lymphoma), a lymphosarcoma, and a mammary gland cancer also showed a higher turnover or uptake of phosphorus than

* See table of elements and their isotopes by Prof. Robley D. Evans, published in this volume.

any of the soft tissues.¹⁰ Cautious exploration showed that in man, leukemia white cells take up more phosphorus than do normal white cells, and that intravenous administration results in a greater effect than oral. Encouraging therapeutic results have followed radio-phosphorus therapy in cases of chronic myelogenous and chronic lymphatic leukemia. The doses given are small, equivalent to 2 to 4 roentgens of whole body irradiation per day, and are controlled by lethal studies on animals and previous knowledge of x-rays. There are no radiation reactions and the simplicity of dosage avoids frequent trips to the x-ray department. In no sense, however, can radio-phosphorus be considered a cure for leukemia.

FIGURE 5. A comparison of the accumulation of radio-phosphorus and radio-strontium in the femurs of two different rabbits. The radio-autograph of the left indicates that radiostrontium was predominantly accumulated in the marrow.

Polycythemia vera (excess of red blood cells) can be readily controlled by small doses of radio-phosphorus, 5 to 7 millicuries intravenously in the form of sodium radiophosphate, followed three weeks later by a similar dose. Six to eight weeks after the first dose the erythrocyte count begins to fall, and may remain normal for a year without further treatments. Encouraging results are also recorded in generalized lymphosarcomatosis, involving chiefly the lymph nodes, and in multiple myeloma, involving the bone marrow.

The late Charles Pecher, a young Belgian physician, found in preliminary experiments¹⁸ that radio-calcium was selectively adsorbed by the bone rather than by the soft tissues. Since radio-strontium behaved like radio-calcium and was more readily prepared in the cyclotron, Pecher gave rabbits intravenous injections of sodium radio-phosphate and of radio-strontium lactate. As may be seen from Figure 6, radio-phosphorus is indicated in a disease like leukemia, which involves both bone marrow and the soft tissues, whereas radio-strontium would logically be used in diseases involving the skeleton. Radio-strontium lactate is also being used in an attempt to mitigate post-operative cancerous metastases, *e.g.*, in osteoclastic (bone-destroying) invasion of the skeleton by breast cancer, and in osteoplastic (bone-forming) metastases in cancer of the prostate. Since 50 to 1,000 times as much radio-strontium is taken up by the bone as by any of the soft tissues, theoretically it becomes possible to irradiate the skeleton and bone marrow selectively with controlled doses of beta rays. In the prostatic case, treatment was followed by a drop in the high serum phosphatase content to nearly normal, which indicates a certain degree of cessation of troublesome and painful bone formation.¹⁴

The normal human thyroid gland, weighing about twenty grams, contains from 5 to 20 milligrams of iodine, which is about 5,000 times the average content of the other body tissues. Thyroxine, a potent hormone exerting control over the rate of metabolism, is produced in and liberated by the thyroid, which has remarkable

selective power of adsorbing iodine and radio-iodine. Hamilton and Soley⁶ administered orally to a group of normal persons and to patients with various thyroid disorders, sodium iodide containing 14 milligrams of iodine with a definite quantity ($10 - 50 \mu\text{C}$) of radio-iodine; cancerous thyroid tissue took up only traces of radio-iodine.⁸

FIGURE 6. The uptake of labelled zinc in the fruit of the tomato plant is demonstrated by the technique of radio-autography. The light areas indicate the regions of maximum deposition of the labelled zinc in slices of the tomato fruit. It can be seen that the seeds apparently accumulate most of the absorbed radiozinc.

The anatomical unit of the thyroid gland is the acinus, with a spherical envelope made of a single layer of specific cells, which encloses a clear, non-cellular material termed "colloid." The grape-like acini, from 20 to 50 microns in diameter, are bound together by numerous strands of connective tissue and are well supplied with blood. Comparing photomicrographs of normal and diseased thyroid sections taken after radio-iodine administration, it was found that normally both the colloid and the thyroid cells take up iodine, while in hyperplastic thyroid tissue it is the colloid that appears to concentrate the recently assimilated iodine to the greater degree. In a case of non-toxic goiter, the labelled iodine appeared to be concentrated in the cells to a greater degree than in the colloid, but in cancerous thyroid the uninvaded tissue took up the iodine, and the cancerous tissue failed to take up any appreciable quantity of the labelled iodine.

Eka-iodine, the newly discovered^{4, 7} radioactive halogen element 85 with a half-life of 7.5 hours, behaves similarly to iodine. It is prepared by bombarding metallic bismuth with alpha particles having an energy of 32 mv, and can be separated from the bismuth by vacuum distillation.

It is not possible to do justice, in this brief outline, to such a novel, potent, and rapidly developing field. However, enough has been said to awaken scientists in all fields to the general nature and importance of the cyclotron, and to some of its direct and indirect uses.

The Betatron: A Generator for High-Energy Electrons and X-rays

PROFESSOR D. W. KERST

University of Illinois, Urbana, Ill.

With the advent of intense interest in nuclear physics which followed Cockcroft and Walton's successful attempt to produce atomic disintegrations by artificially accelerated positive ions, many physicists turned their efforts toward the production of generators for high-speed particles. Not all of those devised could be used for the acceleration of both positive ions and electrons. The electrostatic generator of Van de Graaff can produce either positive ion or electron beams in its linear accelerating tube, depending on the type of source which is installed in the high-voltage electrode. Also the voltage multiplier apparatus used in the early work by Cockcroft and Walton could be used for electrons as well as for positive ions. The energy produced by these types of apparatus to date has reached about 4.5 million volts. To increase this voltage, difficulties in maintaining an electrode and operating a vacuum tube at such an extremely high potential must be overcome.

On the other hand, the cyclotron has been able to accelerate the positive ion of heavy hydrogen to an energy of about 16 million volts, and it has been a very successful instrument for the artificial production of radioactive substances and for the production of neutrons by positive ion bombardment. But the cyclotron cannot give its enormous energy to electrons. Consequently electron experiments requiring large currents had been confined to the energies obtained with the other types of accelerators. The cyclotron principle operates successfully only with particles which have a small velocity compared with that of light, and consequently heavy particles are used to obtain high energy. Since electrons of an energy as small as 0.5 million volts have a velocity which is almost 0.9 the velocity of light, they cannot be accelerated to very high energies by the cyclotron method. However, the betatron principle applies to the acceleration of particles at both classical and relativistic energies; and hence an electron can be started at a very low velocity and acquire a velocity which is within a fraction of a per cent of that of light. In the present betatron 20 million volts are reached.

This method of acceleration, which was successfully accomplished for the first time at the University of Illinois,^{1, 2, 3} shows promise not only of having practical value for x-ray and electron therapy and many other purposes to which x-rays can

be put, but also of opening new fields of research in nuclear physics and in an energy range now found only in cosmic radiation. Some of these applications will be discussed later.

While the general idea of accelerating electrons by magnetic induction seems to be very old, the attempts which have been made to use it were unsuccessful.^{4,5} Before the construction of the betatron, the details of an electron's motion in the betatron were carefully calculated and characteristics of the motion were discovered which made possible the design of a successful accelerator.

The energy is given to an electron stream by the accelerating effect of a time-varying magnetic field. Electrons circulate in essentially one plane between the poles of the betatron magnet which looks somewhat like a small cyclotron. The principle of acceleration is, however, entirely different from that used in the cyclotron, and the betatron's magnet operates on alternating current, whereas the cyclotron's magnet uses direct current.

An electron gun injects electrons into a doughnut-shaped vacuum tube between the poles of the betatron at a time when the magnetic field intensity is small. These electrons circulate between the poles of the magnet while the magnetic field is increasing, and the time rate of change of flux within the orbit produces an electromotive force directed circumferentially along the orbit. The voltage gain per complete trip of the electron around the pole is equal to the instantaneous voltage which would be read on a voltmeter connected to one turn of wire at the orbit which the electron describes. Since the electrons travelling in the vacuum tube can make an enormous number of revolutions while the flux linkage is increasing sinusoidally from zero to its peak value, the energy in electron-volts which is finally obtained is approximately equal to the voltage which would be generated on a secondary coil of the same number of turns placed in the betatron at the position of the orbit. The orbit of the electron is thus similar to the secondary of a transformer, and the great advantage of the betatron is that it is unnecessary to produce the full voltage on a secondary coil and then to apply that voltage to a high-vacuum x-ray tube for the acceleration of the electron. Instead the energy is continually and smoothly supplied to the electron stream.

The chamber or doughnut in which the electrons are accelerated is shown in Figure 1. In the original betatron the path was approximately 80 miles long. This path length is determined by the frequency at which the magnet is excited. Electrons are shot out from the injector at the time A in the figure, and after they have traveled their long path in the doughnut they strike the injector where they produce x-rays and scatter out of the doughnut. The x-rays are produced when the field is large, as at C. Without the disturbing action of the orbit expansion coils, which are shown placed above and below the doughnut, the electron stream would remain in the circle called the equilibrium orbit; however, a sudden pulse of current through these coils spirals the beam outward to the target. In each cycle the injection and expansion are repeated in succession, with a period of three-fourths of a cycle when no electrons are in the doughnut.

While the electron gains energy because of the increasing flux linkage, the magnetic field at the orbit of the electron grows stronger in such a way that the electron stream remains at a fixed radius within the vacuum chamber. Were the field at the orbit not increasing, the electrons would soon spiral toward the outer wall of the doughnut. It is necessary to increase the magnetic field, H , in proportion to the momentum, mv , which is produced by the increase in flux linkage. This arrangement of the magnetic field, then, causes the electron orbit to remain at a fixed radius.

The rate of change of momentum of the electron is, by Newton's second law, the force $d(mv)/dt = f$; and this force is equal to the energy gained per centimeter of

FIGURE 1. The doughnut-shaped vacuum tube in which electrons are accelerated. Electrons are injected at a time, A, in the magnetic cycle, and the orbit is expanded to the target at the time, C. If it is expanded at B or D the energy is less than the maximum which is available.

path. Since the voltage induced in a circuit is $10^{-8}d\phi/dt$, where ϕ is the flux linking the circuit, the voltage gain per centimeter by an electron travelling in a circle about a changing flux is $(10^{-8}/2\pi r)d\phi/dt$, or in ergs per centimeter

$$(e/2\pi rc)d\phi/dt = f, \quad (1)$$

e being the electronic charge and c the velocity of light.

Integrating (1) we get

$$mv = \int_0^t f dt = (e/2\pi rc)(\phi - \phi_0) \quad (2)$$

but for the balance of centripetal and magnetic force

$$\frac{mv^2}{r} = (e/c)Hv, \text{ or } mv = (e/c)Hr \quad (3)$$

Combining (3) with (2) we find that

$$\phi - \phi_0 = 2\pi r^2 H \quad (4)$$

must hold if the electron is travelling in a circle.

For the case of a field and flux produced in an air gap of the same electromagnet, $\phi_0 = 0$ when $H = 0$ and ϕ is always proportional to H . The flux condition (4) is thus automatically fulfilled in the simplest kind of magnetic circuit.

We have assumed that the electron travels in a circle of radius r and have proved that if this is so the flux must fulfill the condition (4). It was necessary to prove the converse which is: given an arrangement of magnetic field and flux satisfying (4), the equilibrium orbit will be a fixed circle. This was done before the original betatron was constructed; and in the development of the complete theory, characteristics of the motion of electrons were discovered which play a vital part in the successful operation of the induction acceleration scheme.

Since the electron path is of the order of 100 miles, it must be possible to form a very stable beam. It is also necessary to find a way to introduce electrons so that they do not strike the injector or fly out of the acceleration region on one of their first few revolutions.

The theoretical treatment³ solved these problems. It was found that stray electrons which had been deflected from the equilibrium orbit by scattering from residual gas in the vacuum tube could be brought back to the orbit by their executing a damped oscillation about this orbit. This characteristic of the motion also plays an important part in the injection of the electrons, as will be seen later.

Figure 2 shows the shape of the laminated pole pieces for the betatron, which

FIGURE 2. Approximate shape of the poles in the betatron. The curvature which they produce in the magnetic field results in the radial component H_r being oppositely directed above and below the plane of the orbit. H_r always forces straying electrons back toward this plane.

succeed in providing the required amount of flux within the orbit to maintain it at a fixed radius and which will produce the damped axial and radial oscillations about the equilibrium orbit. The iron discs in the center of the gap must be of exactly the correct thickness so that (4) is satisfied. The fringing field from between these discs and the curved field resulting from conically shaped pole surfaces have a radial component, H_r , at all points in the gap except in the plane of the orbit. This slight radial field influences straying electrons so that they are always forced back toward the plane of the orbit. The electron thus can oscillate axially with the decreasing amplitude which brings it back to the equilibrium orbit.

The conical shape of the poles means that the field intensity decreases with increas-

ing radius. Provided this decrease is not too rapid, radial oscillation across the equilibrium orbit can also occur. Figure 3 shows the centripetal force, F_c , necessary to hold an electron in a circle of radius r . This curve is hyperbolic, since $F_c = mv^2/r$ and v , the velocity, changes so slowly during several oscillations that it can be considered constant for the present. The force supplied by the magnetic field is $F_m = (e/c)Hv$. If the field H , which is proportional to F_m , is so shaped that F_m is less than F_c when r is less than the radius r_0 of the equilibrium orbit, then the magnetic force is not sufficient to hold the electron in at such a small radius. The electron will thus move

FIGURE 3. Forces acting in the radial focussing process. F_m equals $(e/c)Hv$ for the magnetic force which is supplied to the electron. $F_c = mv^2/r$ is the centripetal force required to hold the electron at radius r . Oscillation occurs about r_0 .

out past r_0 where, if F_m is now greater than F_c , the magnetic force is greater than the required centripetal force and the electron is curved inward toward r_0 .

The straying electron will thus oscillate radially as well as axially about the equilibrium orbit. The damping of these oscillations is due to the slight rise in field strength with time. The effect of the increasing magnetic field is somewhat analogous to that of a stiffening spring which supports an oscillating mass. Theory shows that the amplitude of these oscillations is proportional to $H^{-1/2}$ and hence decreases with increasing field strength.

It is because the oscillation of an electron is damped with a relatively large damping when H is small, that electrons can be injected into the vacuum doughnut from a point close to r_0 so that they do not hit the injector on one of the first few revolutions. This makes possible the process which is used to get the electrons started.

Figure 4 shows the original 2.3-million volt betatron beside the 20-million volt betatron in the laboratory at the University of Illinois. A 600-cycle per second magnetic field was used in the original machine, and because of this fairly high frequency the voltage gain per revolution was large. This facilitated the injection

process and provided a high rate of repetition of charging and discharging the acceleration region with electrons, which is desirable for a high output current. The x-ray intensity produced by the small accelerator is equivalent to the gamma-radiation from a gram of radium, and the electron current which is accelerated is estimated at about 0.03 microampere.

The 20-million volt accelerator was constructed during a leave of absence from the University at the General Electric Company, and it was an intermediate step toward the construction of a betatron following the University's 100-million volt de-

FIGURE 4. The original 2.3-million volt betatron is on the table in front of the 20-million volt betatron in the university betatron laboratory.

sign. The 20-million volt betatron operates at 180 cycles per second and produces a current at the target which can be as high as one microampere. When measured in a thick-walled ionization chamber placed 70 centimeters from the target, the x-ray intensity is about 50r per minute. This intensity is as great as that now commonly used in x-ray therapy; and therapy is one of the possible practical applications of the betatron.

Since the recoil electrons produced when 20-million volt x-rays pass into tissue-like material can penetrate as far as 10 centimeters, a distribution of ionization deep below the surface which is very different from that produced by low voltage x-rays is expected. With 400-kilovolt x-rays the most energetic secondary Compton electron can penetrate only about 1.3 millimeters beyond the point where the x-ray was absorbed. Since it is the secondary electron which produces the ionization in the tissue and which is responsible for the damage done to malignant tissue, this damage is localized at the point of the 400 kv x-ray absorption process. However, the long-range secondary electrons produced by the betatron's x-rays carry this destructive effect far beyond the point at which the x-ray is absorbed. The result is an ionization distribution shown in Figure 5. The ionization at a point beneath the surface of a tissue-like substance is called the depth dose. Percentages of the surface dose are plotted. At ordinary voltages the intensity of ionization falls off below the entrance surface because of x-ray absorption; but at 20 million volts the number of secondary electrons which reach a point beneath but near the surface is propor-

tional to the amount of matter which produces secondaries between this point and the surface. This is so because the long range of the secondaries carries many which are created at the surface to points well below the surface. The graph of the experimental results shows that a maximum ionization occurs at a depth of about 4 centimeters. Since many secondary electrons have low energy they do not penetrate to the extreme depth of 10 centimeters. This ionization distribution should assist in applying the x-ray dose where it is needed in the case of deep malignancies.⁶

FIGURE 5. The distribution of ionization in a heavy Pressdwood phantom having a density equal to that of water.

Of more promise is the direct application of the original electron beam from the betatron to tissue under treatment. These electrons should all penetrate as far as the middle of the body and, according to the estimates of Dr. Philip Morrison of the University of Illinois Physics Department, should produce a maximum ionization 7 or 8 centimeters below the surface. Beyond 10 centimeters there can be no ionization, because this is the extreme range of 20-Mev electrons. This is a very advantageous distribution of ionization for therapeutic purposes.

While the x-rays and electrons from the betatron will undoubtedly find several practical uses, physical researches in new fields are now made possible. Tests have been made on the absorption coefficients of x-rays in various substances at very high energies.⁷ Theoretical predictions have furnished these values in the past, except for a very few instances. Now the results obtained with the betatron confirm these calculations quite well. The important phenomenon observed is that x-rays become less penetrating at voltages above a certain point of minimum absorption coefficient. The minimum absorption for lead is at about 2 to 3 million volts, and for lighter substances this minimum occurs at somewhat higher energies. The rise of absorp-

tion coefficient with photon energy is a result of the increasing production of positron and electron pairs.

Another subject now presenting many problems is the nuclear photoeffect. A stable nucleus can be disrupted by the absorption of an x-ray photon. Usually a neutron is ejected and the remaining nucleus is either a stable isotope of the original nucleus or a radioactive isotope. Just as the photoelectric effect with ordinary light occurs only at quantum energies greater than a certain threshold value, so does the nuclear photoeffect occur only when the gamma-ray photon has an energy, $h\nu$, greater than the threshold for neutron emission. Because of the very precise control of the betatron's energy it has been possible to measure these thresholds for many elements with good accuracy.⁸ One expects the average binding energy of a neutron, that is, the threshold energy, to be about 6 to 8 million electron-volts, but the thresholds found by detecting the radioactivity of the isotopes produced have so far all been higher than 8 million volts. New radioactivities have been found, as might be expected, since certain products may be formed in a betatron which cannot be formed in a cyclotron.

Even at 20 million volts some small cosmic-ray type showers should occur; but since there should be no difficulty in obtaining greater energies, the betatron should make easy some of the problems now being solved by experiments with the feeble cosmic rays. It was for this reason that the University's design for the 100-million volt betatron, which it was intended should be constructed on the University campus, was worked out. In this design the author has attempted to reduce the cost by allowing $\frac{3}{4}$ inch of pole face diameter per million volts. The 20 Mev betatron requires one inch per million volts. The design also reduces cost and simplifies the power problem by employing 60-cycle per second alternating current on the magnet.

The Electrophoretic Study of Proteins and Related Substances

DUNCAN A. MACINNES, PH.D., AND LEWIS G. LONGSWORTH, PH.D.

The Laboratories of The Rockefeller Institute for
Medical Research, New York, N. Y.

The subject of electrophoresis, also frequently called cataphoresis, is concerned with the motion of colloidal particles in an electric field. Since the size of colloidal particles varies from those visible at low magnification in a microscope to those but slightly larger than inorganic ions, such as Na^+ and Cl^- , it is evident that the experimental methods and the theory merge with those applicable to solutions of electrolytes. The connection, at least in its elementary aspects, has been outlined in a recent book by the senior author,⁴⁷ which will be used as a point of departure for the following treatment of recent developments of the subject. These developments have

been important and exciting enough to justify reserving for them all the space in this necessarily brief article.

Electrophoresis has been studied by two principal procedures: (a) the microscopic method and (b) the method of moving boundaries. The first of these has been adequately treated in recent books and review articles,^{1, 2, 47} and will therefore not be described further here. Although it has decided utility in certain cases the microscopic method is giving way, at present at least, to the moving-boundary method, in spite of the fact that the former requires far less elaborate and expensive apparatus. Furthermore the microscopic method is limited to the study of the motion of particles visible in the field of a microscope, whereas the moving-boundary method is not subject to that limitation, and has other advantages that we hope to make evident in the following.

The early work on the moving-boundary method for studying electrophoresis was carried out by Burton,⁸ who used the simple apparatus illustrated in Figure 1. By

FIGURE 1. Early form of U-tube for the electrophoresis of colloids by the moving-boundary method.

first introducing the pure solvent or buffer solution into the U-tube, and then cautiously opening the stopcock *S* between the U-tube and the reservoir *R*, containing the somewhat denser colloidal solution, the electrodes *e-e'* can be surrounded by the solvent, and two fairly sharp boundaries, *a* and *b*, between the solvent and the colloidal solution are formed. On applying an electrical potential these boundaries will, in general, move. A difficulty with the early experiments with this method was that the boundaries were disturbed by convection effects arising from the heating effect of the electric current. Also, early experimenters were limited to the study of colored or turbid solutions, since boundaries involving colorless and transparent substances could not be readily seen. However, Tiselius⁷⁰ was able to obtain useful data on colorless protein materials with an apparatus similar in principle to that shown in Figure 1, by utilizing the ultraviolet absorption of the proteins for following the motion of the boundaries.

Tiselius has also made most of the more recent developments in the electrophoretic method,⁷² with the results that it is now one of the most powerful instruments for research in the field of physical chemistry of proteins and related materials. Its influence is extending deeply into the domains of biology and medicine. Tiselius' main additions to the electrophoretic method are: (a) the use of the "shear" technique in the formation of the initial boundary; (b) the adaption of the Foucault-

Toepler schlieren effect to make the boundaries visible; and (c) the minimizing of convection effects by the use of a low-temperature thermostat. These developments will be discussed in the order given.

The Electrophoresis Cell and Accessories

The cell in which the boundaries are formed and observed during electrophoresis is shown in cross-section in Figure 2A, and consists of the sections I, II, III, and IV.

FIGURE 2. A, electrophoresis cells in cross-section; B, top view of one of the center sections.

These may be slid over one another along the planes *a-a'*, *b-b'*, and *c-c'*. Through the cell runs a U-shaped channel *d-d'* of rectangular cross-section. Figure 2B is a top view of one of the center sections. To form a boundary, the channel is filled with the buffer solution of protein to a level slightly above the plane *b-b'*, about 10 ml of solution being required with the cell of the size usually employed. Section III is then pushed to one side, the excess solution in section II is removed, and this section is rinsed with buffer. The remainder of the cell and the attached electrode vessels to be described are then filled with the buffer. On returning section III to the position shown in the figure, two sharp boundaries between the protein-bearing solution and the buffer solution are formed in the plane *b-b'*. These boundaries may then be displaced from behind the plates, where they cannot be seen, by a means to be described below. Recently cells have been constructed in which the two center sections, II and III, have been combined, yielding a single section double the length of those shown. Such a cell may be filled so that one boundary is formed at the plane *a-a'* and the other at the plane *c-c'*. The filling and manipulation of such a cell is somewhat more complicated than that just discussed, but is fully described in a paper by Longsworth, Cannan, and MacInnes.³⁷ This new design, which is also due to a suggestion of Tiselius, has the advantage that the channels are not inter-

rupted by the plates $b-b'$, and that electrophoretic patterns, to be described later, can be spread over twice the length of the earlier type of cell.

The support for the cell and the electrode vessels, as used at the Rockefeller Institute, together with the mechanism for moving the sections of the cell in relation to each other, are shown in Figure 3. In our apparatus a rack-and-pinion system

FIGURE 3. Electrophoresis cell (new type), electrode vessels, and support.

replaces the pumps utilized by Tiselius for this purpose. The racks r are attached to the shafts s and each may be raised, or lowered, to a position opposite the section of the cell to be moved. Turning the knurled knob k then imparts a horizontal motion to the rack. The latter presses against a metal insert e , which communicates the pressure to the edges of the horizontal glass plates. The center section of the cell shown in Figure 3 is the new tall type mentioned above and, as can be seen in the figure, provision has been made for moving the bottom section as well as the center section. The short sections II and III of Figure 2 are interchangeable with the tall section shown in Figure 3 and, when substituted for the latter, either center section, as well as the bottom section, may be moved, as desired, with the rack-and-pinion system.

After filling the apparatus as described above, the silver-silver chloride electrodes ($E-E'$ of Figure 3) are inserted. For effective operation of these electrodes they must be immersed in a strong chloride solution. This is accomplished by carefully introducing the solution through the silver tubes $t-t'$. These silver tubes, which are

insulated by the glass tubes (*j*), also serve as current leads to the electrodes $E-E'$. We have modified the procedure of Tiselius and our earlier procedure, in that one side of the apparatus is closed, care being taken to exclude air bubbles. This is accomplished with the ground-glass stopper *f* and the stopcock *m*. Closing one side is more convenient than having both sides open, as the latter procedure involves equalizing the liquid levels on the two sides of the system before forming the boundaries. It also permits the use of a convenient method for shifting the boundaries to be described below.

With the cell and electrode vessels filled as described and the two boundaries formed, a potential from a battery applied to the terminals $t-t'$ will then, in general, cause the boundary in one side of the cell to rise and that in the other to fall; or, as will be shown later, a number of boundaries may form on both sides of the cell.

The Simple Schlieren Method for Observation of the Boundaries

As has been mentioned, another important contribution to the electrophoretic method made by Tiselius was the adaptation of the Foucault-Toepler schlieren method for observation of the boundaries. A diagram of the optical system is shown in Figure 4. The image of the horizontal slit *S*, illuminated by the lamp *L*, is

FIGURE 4. Arrangement for observation of the boundaries by the simple schlieren method.

brought to focus in the plane *P* by the lens *D*. The schlieren diaphragm *K*, which is a screen with a sharp, horizontal upper edge, is placed in the plane *P* and may be moved vertically, a micrometer adjustment being used. The cell *E*, in which the electrophoresis is carried out, is placed as near the lens *D* as the thermostat construction permits. The camera objective *O*, placed immediately behind the schlieren diaphragm, is focussed on the cell and forms an image on a ground-glass or photographic plate at *G*.

In the absence of refraction gradients in the electrophoresis cell, all the light is brought to focus in the image of the illuminated slit at *P* and enters the camera objective. If, however, a boundary, *B*, is present in the cell, the refraction decreases with increasing height through the boundary and a pencil of light through this region is deflected downward. If this deflected pencil is intercepted by raising the schlieren diaphragm *K*, it will fail to reach the screen. Thus the region at *G* conjugate to the boundary, *i.e.*, *B'*, appears as a dark band on a light background. A typical case of the use of the simple schlieren technique for locating and following electrophoretic boundaries is shown in Figure 5. The horizontal dark lines are the schlieren bands of the boundaries between an egg albumin solution in a sodium acetate buffer and the pure buffer. The upper and lower photographs are of the boundaries migrating in the anode and cathode sides of the channel, respectively.

Exposures were made at 30-min intervals, and after four exposures the current was reversed. It is of interest that the reversal brought the boundaries accurately back to their original positions. From the distance moved by the boundary in a given time, and the potential gradient in the solution, the *mobility* of the migrating material may be obtained. The potential gradient may be obtained from the conductance of the solution and the current in amperes. Some complicating phenomena must, how-

FIGURE 5. Schlieren bands of a single protein. Exposures were made at 30-minute intervals and the current was reversed after the fourth exposure.

ever, be considered, as will be described below. Modifications and improvements of this simple schlieren technique are considered later in this article.

The Elimination of Convection

As already mentioned, the early study of electrophoresis by the moving-boundary method was made difficult because the boundaries were disturbed by thermal convection. The greatest recent advance in the use of the method is largely due to a simple but brilliant idea which is also Tiselius'. If an electric current is passed through a tube containing a conducting solution, the distribution of temperature inside the tube, and in the wall of the tube, will be somewhat as is shown by curve *a* in Figure 6, *i.e.*, there will be a maximum of temperature in the center of the tube, on both sides of which the temperature will drop to that of the thermostat at the outer surface of the wall of the tube. For ordinary temperatures, and with aqueous solutions, this means that there will be a minimum of density of the solution in the center of the tube, as is also indicated for the special case of a 0.1N acetate buffer at 25° C in curve *b* of the same figure. As a result the heavier solution around the edges of the tube will tend to fall, and that in the middle to rise, and a convection current will result. However, although it is not possible to eliminate the temperature variation if the current is passed, one can choose a temperature at which the *density* variation is a minimum by working at a temperature near that of the maxi-

imum density of the buffer, which, for the solution under consideration, is 2.85°C . If the thermostat temperature t_0 is such that the mean temperature in the tube is 2.85° , the variation of the density across the tube is shown by the line d of the figure. Theoretically and also experimentally, this condition results in the minimizing of effects due to convection.

FIGURE 6. Distribution of temperature and density in a salt solution, in a cylindrical tube, during passage of an electric current.

Recently it has become evident, however, that the variation of density with height in the boundary itself has a decided influence in reducing convection effects. Thus Shedlovsky and Smadel⁶⁰ have shown that it is difficult, if not impossible, to prevent the convection of buffer solutions containing the elementary bodies of vaccinia, which have a particle size somewhat smaller than bacteria and do not appreciably affect the density of the buffer solution. On the other hand, protein solutions which are in molecular dispersion in appropriate buffers yield boundaries substantially free from convection effects (if the temperature is even approximately that of the maximum density of the solution), because of the fact that there is a definite decrease in density on passing from the protein-bearing solution to the buffer solution. Thus, although feeble convection currents may exist, even at the optimum conditions for suppressing them, such currents are apparently stopped by an appreciable gradient of density.

Applications of the Electrophoretic Method to Mixtures and to Separations

In addition to the measurement of mobilities, the electrophoretic method furnishes information as to the purity and homogeneity of protein solutions, and also may be adapted to separation of the components of a mixture. This latter applica-

tion is illustrated diagrammatically in Figure 7. Suppose a mixture of proteins A, B, and C, for which the (positive) mobilities are $u_A > u_B > u_C$, is placed in the cell as shown in Figure 7a. Movement of the bottom center section of the cell to the right will bring the protein and buffer solutions into contact in the plane α . On passage of a current, three boundaries will appear in the upper cathode and in the lower anode sections, as is shown in Figure 7b. It is evident from the figure that

FIGURE 7. Idealized eletrophoresis of a protein mixture.

there is a separation of pure component A in the region between the two leading boundaries on the cathode side and of pure component C between the two slowest boundaries on the anode side. If the electrolysis is continued as indicated, before any large proportions of A and C have been separated, the boundaries will have migrated out of the cell in one case and into the bottom section in the other. However, if the second boundary is given an apparent velocity of zero, as indicated in Figure 7c, while the leading boundary moves through the length of one section, isolation of this section from the others would make possible the recovery of a solution of pure A from the upper cathode portion of the cell. Simultaneously, as indicated, the slowest component would have an apparent negative velocity, and pure C could be recovered from the upper anode section. As a matter of fact, a boundary can be given any apparent velocity desired by a displacement of the entire solution of the cell. In Tiselius' apparatus he displaces the boundaries by withdrawing, with clockwork, a loosely fitting plunger in one of the electrode vessels. We have modified this technique, as shown in Figure 3, by keeping the right-hand electrode vessel closed, and have displaced the solution in the cell by forcing buffer into this side from a syringe *d*, the piston of which is displaced, at the desired rate, by a threaded rod operated by a synchronous clock motor.

Recently it has been found possible to remove the solution from any portion of the cell by inserting a hollow needle and withdrawing the solution into a syringe. The material between any pair of boundaries can be obtained by watching the schlieren bands during the operation.

Improved Optical Systems for Studying Electrophoretic Boundaries

The simple schlieren method described above and illustrated in Figure 4 indicates whether or not boundaries are present in the electrophoresis cell. A boundary, how-

ever, does not consist of a single plane, but is a region in which the properties, such as the composition and the refractive index, vary from that of one solution to that of the other in contact with it. The recent developments of the schlieren method for studying and recording refractive index gradients have made possible the precise study of electrophoretic boundaries. From "electrophoretic patterns" thus obtained the concentrations of the various components, as well as their mobilities, may be determined. The available procedures are the scale method of Lamm,²⁷ the schlieren scanning method developed by Longworth in the Rockefeller Institute laboratory,^{34, 40, 42} and the cylindrical lens (or inclined slit) method of Philpot⁵² and Svensson.⁶⁶

The *scale method* has the advantage of involving relatively simple apparatus, but requires a large amount of tedious labor with a comparator and, having been largely superseded by the methods which follow, will not be described further.

In outline the *schlieren scanning method* is illustrated in Figure 8. As in the simple schlieren method, an image at P of the illuminated slit $S-S$ is formed by the schlieren lens D . The camera lens O is focussed on the electrophoresis cell E and forms an image (full size in the Rockefeller Institute apparatus) on the screen at

FIGURE 8. Diagram of the schlieren scanning method for the photographic recording of gradients of refractive index.

$G-G$. Now if the fluid in the cell is homogeneous this image will be uniformly illuminated. On the other hand, if there is a boundary, B , between, for instance, a protein-bearing solution and a buffer, there will be a region in which the refractive index varies with the height in the cell, and light which would normally pass to P is deflected downward, since the solution with the greater refractive index is on the bottom. If the schlieren diaphragm Q is raised to a point p where it intercepts the most deflected light, a dark band will appear on the screen, conjugate to the region of steepest gradient in the boundary B . Such a band appears in the image $G-G$ at p' .

However, as previously noted, a boundary is a region in which the composition varies from that of one solution to that of the other. The refractive index, n , in such a region changes continuously with the height, h , of the liquid in the cell. The gradient, dn/dh , of refractive index, for each boundary, will thus, theoretically at least, vary from zero to a maximum, and back to zero. In Figure 8 the variation of the gradient, dn/dh , of the boundary B in the cell E , is represented by the density of the shading. The pencil of light passing through the layer having the maximum value of the gradient will be most bent from the normal path and will be the first to be intercepted when the schlieren diaphragm Q is raised. On lifting this diaphragm still further, *i.e.*, to the level q , less refracted pencils of light will also be intercepted and the schlieren band in the image $G-G$ will widen. This obviously can be continued until the whole field has been covered. In the schlieren scanning method this process is made continuous and is recorded photographically. The image

of the cell at $G-G$ is masked by a narrow vertical slit and a photographic plate A is moved in the direction of the arrow at a constant rate across this slit. Actuated by the same mechanism, the schlieren diaphragm Q is given a steady movement upward. The resulting (positive) photographic record for a typical single boundary is indicated by the area $e-f-g$. The displacement of the diaphragm Q from the position P is proportional to the gradient at levels in the cell E conjugate to the edges of the schlieren bands. Thus the contour of the area $e-f-g$ indicates both the position and the magnitude of the refractive index gradients existing in the boundary. Since the photographic plate A was in position a at the time the schlieren diaphragm was at p , a section of the band p' appears at f when the plate has been moved to a' . It will be seen that the usual schlieren bands are narrow sections through the area $e-f-g$. By a system of gears the ratio of the rates of motion of the schlieren diaphragm Q to that of the plate A is given a constant value, such as one to three, and this ratio can be varied by changing the gears. For establishing the base line of the schlieren patterns the position of the diaphragm Q may be read accurately with a micrometer.

The *cylindrical lens method* is convenient in that it makes visible the whole electrophoretic pattern on a screen. It is shown diagrammatically in Figures 9a

FIGURE 9. Diagram of the cylindrical lens method for observation of the electrophoretic patterns.

and 9b, the first being the arrangement as viewed from the side and the second as seen from above. Light from an illuminated horizontal slit to the left of the schlieren lens S is focussed upon a diaphragm D , at right angles to the page. In this diaphragm there is a slit cut at an angle, as is shown at D' in which it has been turned 90° from its position at D . The camera lens C normally projects an image of the electrophoretic cell E on the screen G . However, there is a cylindrical lens H , focussed upon the diagonal slit D , which is interposed between the lens C and the screen G . This cylindrical lens has no effect on the direction of the light beams in the (vertical) direction of its axis, as is shown in Figure 9a, but alters the paths of the light in the horizontal planes, as in the lower part of the diagram, Figure 9b. The diagonal slit D causes the light which is deviated downward by the boundary B in the cell E to be cut off sideways proportionally to that deviation. The cylindrical

lens focusses this sidewise shift on the screen G while the cell E is still in focus vertically. The result of this optical arrangement is that the line $c-d-e-f$ is a plot (actually visible on the screen G at right angles to the page) of the refractive index gradients in the boundary B . In that boundary the values of such gradients are again represented by the density of the shading. A light beam from a given layer in the boundary, d' for instance, passes in the vertical direction, to its conjugate position d , and indicates on the plot $c-d-e-f$ the position of the layer in the boundary, i.e., the abscissas of the plot, as shown in Figure 9a. The downward shift of the beam of light (and therefore the sidewise shift by the angular slit and cylindrical lens) is proportional to the refractive index gradient in the boundary, and yields the values of the ordinates in the plot in the same figure. The principle will be made clear to the reader if he follows the beams $f'-f$, $e'-e$, and $d'-d$ in both figures. These represent respectively light from layers in the boundary where there is no refractive index gradient, an intermediate value, and the maximum value.

Although this cylindrical lens method is convenient for a quick visual examination of the field and for control of electrophoretic separations, it has the disadvantage that adequately corrected cylindrical lenses are not commercially available. The electrophoresis equipment in our laboratory is now arranged³⁶ so that either the cylindrical lens or scanning procedure may be used interchangeably, the former for visual inspection of the patterns during an experiment and the latter for the permanent photographic records on which the analyses are based.

The Determination of Mobilities and Concentrations from Electrophoretic Patterns

A reproduction of a typical electrophoretic pattern obtained by the schlieren scanning method of normal human blood plasma is shown in Figure 10. The left and right sections of the figure are the patterns from the rising and descending boundaries respectively. The different peaks are those produced by albumin (A), the α_2 , β , and γ globulins, and fibrinogen (ϕ) as marked. Incidentally, until the electrophoretic work of Tiselius it was not known with certainty that there exists more than one globulin in human blood.

From such electrophoretic patterns it is possible to obtain the mobility of the constituent forming the leading boundary if the following data are available: (a) the specific conductance, K_p , of the protein solution, (b) the current, I , in amperes, and (c) the time, t , during which the descending boundary has swept through the volume V . With these data the mobility, U , may be computed with the aid of the formula

$$U = \frac{VK_p}{It}$$

"Mobilities" for the slower components may also be computed from the patterns and are useful for identifications. Quantitatively they are subject to small errors.

In order to obtain the volume it is necessary to know the starting position of the boundaries, and the following procedure is used. The initially sharp boundaries between the protein solution and buffer, which are out of sight because they are hidden behind the sliding plates of the cell, are brought into view by forcing a small volume of buffer into one side of the electrophoresis apparatus. The schlieren band due to the initial boundary is recorded on the photographic plate. The result is shown on the strips s , s' of Figure 10. The electrophoresis is then carried out for the measured time, t , the plate is shifted slightly in the camera, and the scanning process, as described above, is carried out. The distance, h , between the starting position and that of a given boundary may then be measured with a comparator. The position of a boundary, for instance, that of the albumin, A, in Figure 10b, may without serious error be assumed to be that of the maximum ordinate. Mobilities

computed from data obtained from rising boundaries are found to be, under the conditions of these experiments, over 10 per cent greater than those found from descending boundaries. The reasons for this discrepancy will be discussed below.

The concentration of a component may be obtained from the area formed, in the schlieren pattern, by a given boundary, if the coefficient K , connecting the refractive index increment with the concentration, is known. However, it is very important

FIGURE 10. Electrophoretic patterns of a sample of normal blood plasma, including records of the base line of the pattern, and the starting position of the boundaries.

for this purpose to establish the base line of the pattern. This will be the position, on the pattern, of undeviated light, including any slight refractions due to irregularities of the cell walls, and is located as follows. Before the boundaries are in view, the schlieren diaphragm, Q , of Figure 8, is brought to a position just below P , *i.e.*, below the normal image of the slit S , and the scanning process, as described, is then carried out until the diaphragm has passed P . A typical result of this process is shown in the strips τ and τ' at the top of Figure 10. From the readings of the micrometer head registering the position of the schlieren diaphragm Q of Figure 8, and the ratio connecting the rates of motion of the diaphragm with the distance, z , along the plate, the reading of the micrometer head at which the undeviated light is intercepted may be interpolated. If there are irregularities of the cell wall this reading may be found as a function of the height, h , in the cell. When the protein pattern is taken by the schlieren scanning method, the positions along the vertical direction (as reproduced in Figure 10) are also known in terms of readings of the

micrometer head. The lower edge of the electrophoretic pattern, *i.e.* the base line, can thus be accurately plotted. In determining the area due to a given component with a planimeter it is necessary to make a more or less arbitrary separation, a vertical line being drawn from the lowest point between two adjacent peaks, because of the fact that the refractions due to the different boundaries frequently overlap.

Some "Boundary Anomalies"

The type of phenomenon to be discussed in this section is illustrated in Figure 11, which represents electrophoretic patterns of a 1.36 per cent solution of ovalbumin

FIGURE 11. Electrophoretic patterns of a 1.36 per cent solution of ovalbumin in a 0.1*N* sodium acetate buffer at pH 3.92 and 0°.

at pH 3.92 in a 0.1*N* sodium acetate buffer. It will be seen in this figure that two peaks or maxima are evident in the patterns of both the rising and descending boundaries, but that the patterns are far from being mirror images of each other. This may possibly be an extreme case, but is all the more useful in illustrating deviations from ideal behavior and in testing the validity of the interpretation to be given below.

The deviations, or so-called "boundary anomalies," illustrated by these patterns are as follows. (1) The rising boundary *r* is much sharper than that, *d*, descending into the protein solution. (2) The boundary *r* has swept through a larger volume V_r , than that, V_d , of the boundary *d*. (3) The total shaded area of Figure 11a is equal to that of Figure 11b, but the partial area A_r under the rising boundary *r* is less than that, A_d , for the descending boundary *d*. Since these areas are proportional to the concentration changes at the boundaries, it is apparent that the change is less at the rising boundary than at the descending one. Also (4), the concentration distribution in a boundary is not, in general, symmetrical about the maximum, as is shown by the shapes of the peaks *d* and *r*.

These deviations may be explained, with the aid of Figure 12, as follows.^{38, 40} In practice the protein solution is prepared by dialysis against a buffer solution. A difference of salt composition, due to the Donnan equilibrium, exists between the two solutions when dialysis is complete. Moreover, the protein solution contains conducting constituents, the protein ions, that are not present in the buffer solution. When passage of a current causes a boundary between two such solutions to move

from *a* to *d* of Figure 12, for example, there is found in the intervening volume V_d a buffer solution of composition $[B']$. This composition has been "adjusted" by the passage of the electric current, in general, to a value different from that of B .^{*} The boundary ϵ , which moves very slowly, thus forms between two solutions of the same buffer, but at different concentrations, and is quite evident in Figure 11. With the boundary r moving upward into the buffer solution, there is a similar but more complicated adjustment of the composition of the protein solution which replaces the buffer as the boundary rises. The resulting concentration boundary δ , between the

FIGURE 12. Diagram of the electrophoresis cell illustrating the relative positions of the boundaries.

solutions P and P' , of Figure 12, also moves very slowly under the influence of the current. The δ boundary, also shown in Figure 11, is much more visible than the ϵ boundary, because the former involves a gradient of protein concentration whereas the latter does not. This also has the effect of reducing the area A , under the rising boundary. These δ and ϵ boundaries were at first thought to be due to electrophoretically inert components present in the solution. There is, however, ample evidence at present of the adequacy of the explanation given above. In some cases the δ and ϵ boundaries may be suppressed by an appropriate selection of the concentration of the buffer solution with which the initial boundary is made, as has been shown by Longworth and MacInnes.⁴⁰

Since the specific conductance of the protein solution P has been found experimentally to be less, in general, than that of the adjusted buffer solution, the electric field is greater in the protein solution than in the buffer, and variations of this field thus exist at the descending boundary d . The protein ions in the dilute uppermost layers of the boundary d are therefore in weaker fields than are those in the concentrated layers and thus tend to lag behind, causing the boundary to become diffuse, as is shown in Figure 11b. In the case of the boundary r rising into the buffer solution, the specific conductance of the "adjusted" protein solution is less than that of the buffer, so that the dilute, slowly moving protein ions tend to be overtaken by the faster, concentrated ones, with the result that this boundary tends to remain sharp, as illustrated by Figure 11a. Due to these field gradients at the boundaries, and in some instances to pH gradients also, the distribution through a boundary may be unsymmetrical about the ordinate passing through the maximum of the re-

^{*} This adjustment is understood for some simple cases,^{16, 26, 33, 81} but the theory for the more complicated systems frequently encountered in practice has not been developed.

fractive index gradient curve. This lack of symmetry, shown clearly by the boundary d of Figure 11b, has been studied by Tiselius and Horsfall.⁷⁶ Assuming a proportionality between refractive index and protein concentration, it is apparent that in such cases the position of the maximum gradient is not identical with that of the ordinate which divides the area under the curve into two equal parts. The position of the latter ordinate is the better value to use in mobility computations, since it is approximately the position the boundary would have if it retained its original sharpness. The precise location of an unsymmetrical boundary requires an integration of the concentration-distance curve.³⁵ Computations for some typical cases show that the position of the ordinate dividing the gradient curve into equal parts differs from the true value by at most 1 per cent, whereas the position of the maximum ordinate may be in error by as much as 20 per cent.

The Results of Investigations Using the Electrophoretic Method

In the short time since Tiselius announced his improvements of the electrophoretic method quite a number of investigations have been made in which the procedure has been applied to problems arising in connection with the chemistry of proteins and related substances, and in biology and medicine. Some typical examples are outlined below.

A word of warning to those considering the application of the method to specific problems may not be amiss. It is our experience that quick solutions of such problems are not to be expected. Usually it is found that a few electrophoretic patterns only suggest further work, and that the answer to a given question is reached only after many patterns have been collected and all the relevant chemical, physical, and biological information has been used. Usually the patterns suggest chemical or biological experiments which in turn require further electrophoretic experiments. However, the additional information yielded by the electrophoretic method frequently leads to solutions of research problems that cannot be obtained otherwise, or are arrived at with great difficulty.

(a) **The Purification of Ovalbumin.** An example of the utility of the electrophoretic method for obtaining information as to what is actually going on during a familiar procedure, *i.e.*, the purification of ovalbumin by the method suggested by La Rosa²⁸ will be illustrated with electrophoretic patterns, which are given in Figure 13. These are from a research on egg white by the authors and Dr. R. Keith Cannan.³⁷ In that figure (a) is for the untreated egg white at pH 3.92. Comparison with patterns obtained with the separated (or partially separated) components has made possible the identification of the sources of the various peaks as: O, ovomucoid (including the δ and ϵ effects); A and G₃, ovalbumin and one of the three globulins, C₁, conalbumin, and G₁ and G₂, globulins. At this pH value G₃ has the same mobility as ovalbumin, as will be shown below. This is only one of many examples we have encountered which indicate that the number of components in a mixture must not be judged from the number of peaks in the electrophoretic patterns (or the number of schlieren bands) obtained at a single pH value. If now the conventional separation is made into "albumin" and "globulin" fractions by adding to the egg white an equal volume of saturated ammonium sulfate and filtering, the resulting electrophoretic pattern of the soluble fraction is shown in (b) of Figure 13. The pattern shows peaks corresponding to all the constituents indicated in (a) with the exception of globulin G₂. The pattern for the corresponding insoluble or "globulin" fraction is given in Figure 13 (d). That material also shows peaks corresponding to all the constituents appearing in the pattern for egg white. However, there has been concentration of the albumin components in the filtrate and of the globulins in the precipitate.

Figure 13 (f) shows the effect of crystallization of the "albumin" fraction, after bringing this solution to pH 4.6 by adding acetic acid. The globulin G₁ has dis-

FIGURE 13. Electrophoretic patterns of the various fractions arising in the preparation of crystalline ovalbumin.

appeared, and conalbumin, C_1 , is present in greatly decreased amount. That the ovomucoid, O , is reduced is shown by comparing the $O + \epsilon$ peaks in (a) and (b) with the ϵ peak in (f). The electrophoretic patterns, Figure 13 (g) and (h), show the effect of two further crystallizations. In the former, a scarcely perceptible amount of conalbumin is present, and in the latter it has practically disappeared. It will be observed that the peaks marked δ and ϵ persist unchanged in patterns (g) and (h). As already mentioned, these are due to concentration changes near the original position of the boundaries and do not arise from any single component. After three crystallizations, therefore, the patterns show that substantial purification of the ovalbumin has been attained. This is in agreement with the observations of Sørensen and Høyrup,⁶³ and of Hektoen and Cole.¹⁵

Of interest in this connection is the pattern of the filtrate obtained after crystallization of the "albumin" fraction, Figure 13 (b). This is shown in Figure 13 (c), and indicates relatively large proportions of the conalbumin, C_1 , and ovomucoid, O , and a correspondingly small amount of ovalbumin, A , indicating once more that the crystallization serves as an effective means of separation of the chief constituent from its impurities.

(b) **The Complexity of the Proteins of Egg White.** Before the electrophoretic investigations it was not known that egg white contains at least three globulins. In addition, the method has shown that the other proteins, albumin, conalbumin, and ovomucoid, are complex. The type of complexity is different for the three substances.

Although *ovalbumin* forms small but well defined crystals, the electrophoretic patterns indicate that it has two components, A_1 and A_2 , which have different mobilities at most pH values. This was first pointed out by Longsworth³⁴ and has been observed independently by other workers.⁷³ Some electrophoretic patterns of at least three-times recrystallized ovalbumin are shown in Figure 14. It will be seen that

FIGURE 14. Electrophoretic patterns illustrating the complexity of crystalline ovalbumin.

at low pH values and at very high ones there is only one peak or maximum in the patterns, but at intermediate pH values there are two. There appears to be some variability in the relative amount of the component A_2 , but it has been found in all the many samples of ovalbumin that we have examined, although the material has been prepared from eggs from diverse sources, and with some variations in the manner of preparation. The component A_2 does not appear to be, as was first conjectured, an intermediate step in the usual processes of denaturation. The native recrystallized ovalbumin remaining after a large part of the material had been denatured by means of heat, acid, alkali, and surface denaturation yielded patterns practically indistinguishable from the starting material.

Conalbumin was studied electrophoretically at a series of pH values, with the results, for the rising boundaries, shown in Figure 15. At pH 3.92 only one component is indicated, whereas at the higher pH values there are two maxima (other than that due to the δ effect), indicating two components which we will designate by C_1 and C_2 . It will be seen that the proportion of the component C_2 decreases with increasing pH. Conalbumin in egg white itself, at least above pH 4, shows only one component with mobilities corresponding to the constituent C_1 . If, however, the diluted egg white is dialyzed for three days at pH 3.6 and then again dialyzed at pH

FIGURE 15. Electrophoretic patterns illustrating the complexity of conalbumin as prepared from egg white.

4.6 and an electrophoretic pattern obtained, maxima corresponding to the two components, C_1 and C_2 , are observed. It thus appears that in egg white, as well as with the separated conalbumin, the transformation from C_1 to C_2 takes place below pH 4, the latter being the stable form below that pH value and the former being stable above it, at least in dilute salt solutions. Evidence that there are two components with different molecular weights in purified conalbumin was furnished by the ultracentrifuge. The experiments were carried out by Dr. A. Rothen of the Rockefeller Institute.

The indication that *ovomucoid* is complex is furnished by the observation that it shows "reversible boundary spreading" in an electric field. The phenomenon was described by Tiselius and Horsfall.⁷⁵ In such cases an initially sharp boundary will become diffuse as the electrolysis proceeds, but when the current is reversed will progressively recover some of its initial sharpness. The simplest explanation of this phenomenon is that the protein molecules forming the boundary have a range of mobilities instead of a single value. The boundaries of the ovomucoid of egg white exhibit this type of spreading to a marked extent. This is illustrated by the superimposed tracings, shown in Figure 16, of the electrophoretic patterns obtained dur-

ing the electrolysis of a 1.18 per cent solution of ovomucoid in a 0.1*N* sodium acetate buffer at pH 5.32. The initial boundary positions in the two sides of the channel were at a and a' . The pattern contours after electrolysis for successive periods of 4500 seconds at 5.81 volts/cm are indicated by the full curves r_1 , r_2 , and r_3 for the rising boundary and d_1 , d_2 , and d_3 for the descending boundary, respectively. After the third period the current was reversed and the dashed curves represent the con-

FIGURE 16. Electrophoretic patterns illustrating the reversible boundary spreading of ovomucoid.

tours after two more intervals of 4500 seconds. A comparison of the full and dashed curves for each time interval indicates that, although the boundaries spread as they migrate away from their initial positions, this spreading is almost completely reversed on changing the direction of the current. Since some spreading of a boundary, due to diffusion, occurs independently of the electrophoresis, the boundaries do not recover all their original sharpness. The substantial recovery that is effected indicates, however, that most of the boundary spreading is due to electrical inhomogeneity of the ovomucoid. Similar spreading of the ovomucoid boundaries has been observed at other pH values. However, in no instance has there been indication of resolution into two or more separate boundaries.

To summarize, the proteins ovalbumin, conalbumin, and ovomucoid illustrate three different types of electrophoretic complexity. Ovalbumin shows two components, their amounts being quite independent of pH and other variables. Conalbumin has two components, the relative amounts of which vary with the pH. Ovomucoid shows a range of mobilities, and possibly therefore a range of composition or of molecular shape.

(c) **The Electrophoretic Study of Blood.** Of the protein-bearing solutions the most interesting and important would appear to be human blood. Stenhagen⁶⁴ has obtained the mobilities of the main constituents of human blood plasma by the schlieren band method. However, by the schlieren scanning procedure it has been possible to obtain not only the mobilities but also the concentrations of the protein constituents in the sera and plasmas. The following is a brief outline of a portion of the work done in that field by the authors and by Drs. Shedlovsky and Scudder in the laboratories of the Rockefeller Institute.^{42, 59} Figure 10 shows the electrophoretic patterns for the rising and descending boundaries of normal human blood plasma. As already explained, there are peaks for albumin A, the three globulins, α_2 ,* β , and γ , and for fibrinogen, ϕ . The electrophoretic patterns obtained from the blood of normal healthy individuals are strikingly alike. In the descending boundary pattern there is the interesting " β globulin disturbance," indicated by the sharp spike. The explanation for this phenomenon appears to be that when it is separated from the albumin and the α globulins a change takes place in the β globulin, producing convection currents and, in consequence, regions of total reflection. In some cases the β globulin, or accompanying lipid material, precipitates, yielding a turbidity which travels with the β boundary.

In the course of this work the electrophoretic patterns of the plasmas and sera of patients suffering with a wide variety of diseases were studied. Some of these patterns differ so much from that of normal blood that any interpretation was at first very difficult. However, order has begun to emerge, and tentative conclusions as to the meanings of patterns may be made. In Figure 17 the patterns obtained from the sera of patients suffering from various pathological conditions are compared with that from normal serum. One condition common to all these pathological conditions was fever. It will be observed that in each case there is a marked increase of α globulin. This increase of α globulin has been invariably found in cases of infections accompanied by fever, and, more generally, in conditions involving inflammation or destruction of tissue.^{5, 59}

Figure 18 contains the electrophoretic patterns of other samples of pathological sera and plasmas, including that of normal plasma, *a*, for comparison. Of these patterns, *b* is that of the plasma of a multiple myeloma patient. The most marked difference between this pattern and that of normal plasma is the great increase of the peak due to β globulin, or, more exactly, of material moving with the mobility ascribed to β globulin, since a peak may arise from two or more materials moving with essentially the same velocity. The more recent work of Kekwick²⁴ and of Gutman and his associates¹² indicates that the enhancement of the β globulin peak in Figure 18*b* is probably due to one of the Bence-Jones proteins frequently associated with this disease.

It is our observation and also that of Blix⁶ that lipid material may be carried with the β globulin, probably in loose chemical combination. This is indicated by the patterns *c* and *f* of the figure, from a case of obstructive jaundice. The first of these is directly from the plasma, whereas the second was obtained from the plasma after it had been extracted with ether to remove the fatty material. It will be ob-

* Recently another globulin, designated as α_1 , has been observed³⁶ to separate from the albumin in patterns obtained at pH 8.6, using a buffer consisting of 0.1*N* sodium diethylbarbiturate and 0.02*N* diethylbarbituric acid. The use of this buffer also has the important advantage that there is a separation of the peak of the γ globulin from those due to the δ and ϵ boundaries (see reference 38).

served that the peak due to the globulin has been much reduced by this procedure.

(d) **The Isolation of a Pure Hormone.** An example from the work of Shedlovsky *et al.*⁵⁸ of the utility of the electrophoretic technique in connection with the identification and purification of a biologically active material is that of the isolation of metakentrin, *i.e.*, the luteinizing hormone of the anterior lobe of the pituitary gland. By application of the usual techniques a material was obtained that gave at pH 7.85 the electrophoretic pattern shown in Fig. 19 A, which indicates three

FIGURE 17. Electrophoretic patterns of some normal and pathological human blood sera.

components. After sufficient separation of the electrophoretic boundaries it was possible to isolate two fractions, one containing the major component and the other the two minor ones. This was done by inserting the needle of a syringe and withdrawing the material desired, using the schlieren bands to control the operation. The biological activity was found to be entirely in the major component. Electrophoresis experiments were performed over the pH range 4.5 to 8.0, and it was found from a plot of the mobilities against the pH values that the major component has an isoelectric point, *i.e.*, zero mobility, at pH 7.45. This information made it possible to secure the pure hormone by isoelectric precipitation, which yielded the electrophoretic pattern shown in Figure 19 B. The fact that the material shows only one peak in the pattern over its pH-stability range is a necessary, but not suf-

ficient, indication of its purity. Ultracentrifugal, solubility, and biological investigations, however, contributed additional evidence that a single pure hormone had been separated.

FIGURE 19. Electrophoretic patterns at pH 7.85 of a pituitary hormone, metakentrin. A, before final purification; B, after final purification.

Further Investigations Using Electrophoretic Technique

The following is a brief, but fairly complete, outline of investigations, using the Tiselius electrophoretic technique, not described above.

Electrophoretic analyses of normal and pathological human sera have been made by Kekwick,^{22, 23} and by Luetscher.^{43, 44} The proteins of other body fluids and tissues have been examined electrophoretically by Hesselvik,¹⁹ by the authors,³⁹ and by Luetscher in the work mentioned above. In addition to the proteins normally present in such materials, high molecular weight nucleic acids and polysaccharides are frequently observed. These, too, are subject to electrophoretic characterization, as has been shown by Seibert, Pedersen, and Tiselius,⁵⁵ by Hesselvik,¹⁸ by one of the authors in collaboration with Meyer and Chaffee,⁴⁸ and by Hall.¹³ It is of considerable interest that the electrophoretic patterns of materials containing both protein and nucleic acid, or polysaccharide, frequently indicate the existence of complexes between the components. This is illustrated by the work of Stenhagen and Teorell⁶⁵ on mixtures of serum albumin and thymus nucleic acid, of Seibert and Watson^{54, 56} on the components of the tubercle bacillus, of Chargaff, Ziff, and Moore⁹ on mixtures of heparin and plasma, and our own work on ovalbumin-yeast nucleic acid mixtures.⁴¹

The application of electrophoretic analysis as a control of the salting-out methods for the separation and purification of proteins is illustrated by the work of Cohn and his associates.¹⁰ They find a parallelism between the mobilities, at alkaline reaction, of the horse-serum proteins and the ease with which they may be salted out. The ranges of salt concentration through which precipitation of components occurs are, however, rather broad and overlap seriously. Svensson⁶⁷ has extended this observation to the sera of other animals and has further shown that the classical eu- and pseudo-globulins of serum contain all the electrophoretically separable globulins, *i.e.*, α , β , and γ globulin, in much the same proportions.

In the field of immunology the pioneer electrophoretic studies of Tiselius⁷¹ and of Tiselius and Kabat⁷⁷ on hyperimmune sera showed that the antibody globulin generally migrated with a mobility similar to that of γ globulin, and hence appeared in the pattern as an enhancement of the latter. Their work and that of Pappenheimer, Lundgren, and Williams;⁵¹ of Kekwick and Record;²⁵ of Fell, Stern, and Coghill,¹¹ and of van der Scheer, Wyckoff, and Clarke^{78, 79} shows, however, that there are instances in which the antibody has a mobility intermediate between the mobilities of β and γ globulins. The last-mentioned work affords an excellent example of the use of electrophoresis in the analysis and production control of antisera. In antisera prepared by Thompson and Melnick⁶⁹ against a gonadotropic hormone, the antibodies were present in the γ globulin fraction. The work of Newell and his associates⁵⁰ indicates that the antibodies in certain allergies are also γ globulins. The "proteins" from ragweed responsible for the allergic reaction have been investigated electrophoretically by Abramson, Moore, and Gettner³ (see also ⁴).

Electrophoretic patterns of the sera of the more common laboratory animals have been obtained in connection with the immunological and salting-out studies mentioned above. Rat sera have been studied by Jameson and Tostado.^{20, 21} Patterns of mouse sera have been obtained by Bourdillon and Lennette⁷ in connection with their studies of the influenza virus.

We have already discussed an application of the electrophoretic method in the field of hormone chemistry, namely, in the purification of metakentrin. Other studies on the pituitary hormones are those of Shipley, Stern, and White⁶² and of Li, Lyons, and Evans^{30, 31, 32} on the lactogenic agent, and of van Dyke and his associates⁸⁰ on the oxytocic, pressor, and antidiuretic principles. Hall¹⁴ has made an electrophoretic study of insulin.

With the aid of electrophoretic studies Tiselius, Henschen, and Svensson⁷⁴ have shown that the crystalline enzyme, pepsin, is an acid protein, *i.e.*, it migrates as an

anion at all accessible values of pH. Herriott, Desreux, and Northrop¹⁷ have further shown that samples of pepsin can be prepared that are electrophoretically homogeneous and have a maximum enzyme activity. Ribonuclease and cytochrome C are other enzymes that have been characterized electrophoretically, the former by Rothen⁵⁸ and the latter by Theorell and Akesson.⁶⁸

The difficulties that have been encountered in the application of the electrophoretic method to vaccinia (elementary bodies) have already been mentioned⁶⁰ and are further illustrated by the work of McFarlane.⁴⁵ Important results have, nevertheless, been obtained with this material by Shedlovsky and Smadel.⁶¹ No comparable difficulties, on the other hand, have been experienced in the electrophoretic examination of the virus proteins, *i.e.*, bushy stunt virus by McFarlane and Kekwick,⁴⁶ of alfalfa mosaic virus by Lauffer and Ross,²⁹ and of papilloma virus by Sharp and his associates.⁵⁷ Miller and Stanley⁴⁹ have used electrophoresis in a comparative study of tobacco mosaic virus and certain of its derivatives.

CONCLUSION

The authors have failed if they have not indicated that the field of electrophoresis is rapidly progressing both in the development of the method and in its application. They do not profess to have said the last word on the subject, and will be disappointed if this chapter is not somewhat out of date by the time it appears.

High-speed Centrifugation

Ultracentrifugal Analysis and the Centrifugal Fractionation and Concentration of Molecular Particles

E. G. PICKELS

Laboratories of the International Health Division of The Rockefeller Foundation, New York, N. Y.

Introduction

Centrifugal force was used at least 1000 years ago for extracting tung oil, and today it is still serving industry in many important roles, a notable example being that of the common cream separator.⁸¹ In certain fields of research, the familiar motor-driven laboratory centrifuge has become indispensable as a simple tool for fractionating the particulate matter suspended in liquid media. Within comparatively recent years there have appeared new implements of research in the form of high-speed centrifuges capable of separating from solution small particles of molecular dimensions, *e.g.*, proteins and filterable viruses.

With regard to the origin of this new field of investigation, the most important historical event was the development of a small, electrically-driven "optical centrifuge" by Svedberg and Nichols¹³² at the University of Wisconsin in 1923. Svedberg and Rinde¹³⁴ used the machine to study size distribution among gold sols and proposed for it the name "ultracentrifuge," denoting an instrument by means of which sedimentation in a centrifugal field could be measured quantitatively. However, in re-

cent years it has become the practice of many investigators to associate the term "ultracentrifuge" with any type of high-speed centrifuge rather than with the original connotation of quantitative measurement.

All significant developments in the field of ultracentrifugation prior to 1940 have been reviewed in "The Ultracentrifuge," compiled by Thé Svedberg and Kai O. Pedersen, in cooperation with J. H. Bauer and E. G. Pickels, G. Boestad, E. O. Kraemer and J. B. Nichols, O. Lamm, A. S. McFarlane, and R. Signer.¹³³ A thorough bibliography of the literature pertaining to the construction and applications of high-speed centrifuges is included. At the end of the present paper will be found a less extensive but more up-to-date bibliography, along with an index arranged according to subject. Especial attention has been given to recent improvements in optical methods and to developments and experiments concerned with the newer electrical and air-driven centrifuges.

Theory of Convection-free Sedimentation and the Determination of Particle Size and Weight

The concentration distribution of small, monodisperse particles settling through a fluid in a uniform field of force has been investigated theoretically by Mason and Weaver⁶⁶ and by Weaver.¹⁴⁷ Expressions giving the concentration of diffusible particles at any time and position within a liquid subjected to a centrifugal field of force have been contributed by Faxen,³⁵ Lamm,⁵⁵ and Archibald.³

Svedberg¹²¹ has derived mathematical equations which show the relationship existing between the molecular weight of homogeneous monodisperse particles and their sedimentation characteristics under certain special conditions in an ultracentrifuge. These equations apply strictly only to dilute solutions of particles which are large in comparison with the molecules constituting the medium, and which are electrically neutral with respect to the medium. Consider a suspension of particles of molecular weight, M , revolving in a centrifuge at an angular velocity of ω radians per second. Assume that the particles under observation are far enough from the bounding surfaces of the fluid to be uninfluenced by alterations of particle concentration in these regions. The net force acting on a mole of these particles at a distance x from the axis of rotation is simply the difference between their combined centrifugal weight and the buoyancy exerted by the displaced medium, *i.e.*,

$$F_c = M\omega^2x - M\frac{\rho\omega^2x}{\sigma} \text{ or } F_c = M\omega^2x - MV\rho\omega^2x \quad (1)$$

where ρ is the density of the medium and σ is the density of the particles. The latter is equivalent to $1/V$, where V is the partial specific volume of the particles. Disregarding the negligible forces due to the slight acceleration in the speed of the particles with time, the force F_c is exactly counterbalanced by a frictional force F_s , which is proportional only to the sedimentation velocity of the particles and to a factor dependent upon the extent and shape of their surface. The frictional force on each mole per unit speed is called the frictional coefficient f_s . Thus,

$$F_c = M\left(1 - \frac{\rho}{\sigma}\right)\omega^2x = F_s = f_s dx/dt \quad (2)$$

where t is the time. In this expression $\frac{dx}{dt}\left(\frac{1}{\omega^2x}\right)$ is the sedimentation velocity per unit field of force, and is usually denoted by s . Rewriting the equation, we have

$$s = \frac{M\left(1 - \frac{\rho}{\sigma}\right)}{f_s} \text{ or } sf_s = M\left(1 - \frac{\rho}{\sigma}\right) \quad (3)$$

The diffusion constant D , which expresses the rate at which the particles will diffuse, is also inversely proportional to a molar frictional coefficient f_D :

$$D = \frac{RT}{f_D} \quad (4)$$

R is the gas constant and T the absolute temperature. A discussion of methods for measuring D are given in a recent paper by Neurath.⁷⁸ It should be noted that a change in the mass of particles does not affect the diffusion rate directly but only in so far as it is associated with a change in the frictional coefficient. This is true since the frictional forces are large in comparison with the inertial forces involved. Theoretical evidence, as well as experimental evidence based on sedimentation at different speeds, justifies the assumptions that the random orientation of molecular particles during either diffusion or sedimentation is not appreciably altered, and that for the same medium at the same temperature T , $f_s = f_D$ to a very close approximation. Eliminating the frictional coefficient from Equations 3 and 4, one obtains Svedberg's formula for the molecular weight as determined by what is known as the sedimentation velocity method:

$$M = \frac{RTs}{D\left(1 - \frac{\rho}{\sigma}\right)} \quad (5)$$

In general, sedimentation and diffusion experiments are performed at different temperatures, and for the sake of comparisons, it is customary to correct measured values of D and s to some standard temperature, usually $T = 293^\circ$ Absolute. Svedberg has standardized conditions even further, and expresses each measurement of sedimentation in terms of a "sedimentation constant," s_{20} , which is the rate the material would have in a hypothetical medium having the density and viscosity of water at 20° C or 293° Absolute:

$$s_{20} = \frac{\eta(\sigma - \rho_{w20})}{\eta_{w20}(\sigma - \rho)} \quad (6)$$

where η denotes viscosity. Sedimentation constants are usually given in S or Svedberg units, *i.e.*, in units of centimeters per second per unit field of force multiplied by 10^{13} . For example, in the case of hemoglobin:

$$\begin{aligned} s_{20} &= 4.4 \times 10^{-13} \text{ cm/sec/dyne/gm} \\ &= 4.4 \times 10^{-13} \text{ cm/sec/unit field of force} \\ &= 4.4 \times 10^{-13} \text{ sec} \quad (\text{absolute units}) \\ &= 4.4S \quad (\text{Svedberg units of sedimentation}) \end{aligned}$$

If the particles are known to be spherical and the value of σ to be unaffected by hydration or solvation, the molecular weight can be determined without the diffusion constant by substituting into Equation 2 the value of the molar frictional coefficient for spherical particles:

$$f_0 = 6\pi\eta N \left(\frac{3M}{4\pi N\sigma} \right)^{1/3} \quad (7)$$

in which N is the Avogadro constant. For this expression, we are indebted to G. G. Stokes,¹²⁰ who proved theoretically that the resisting force against a slowly moving small sphere is equal to a constant (6π) multiplied by the product of its radius, its velocity, and the viscosity of the medium. It is the linear relationship with velocity which renders the above expression valid even when the particles are subject to

Brownian movements, and the measured sedimentation rate is actually a resolved averaged rate of many short movements in many directions. A more direct method of computing the radius a of a spherical particle, after which the value of M can be easily obtained, is to apply Stokes' law in the following form:

$$a^2 = \frac{9\eta s}{2(\sigma - \rho)} \quad (8)$$

The sedimentation equations given above refer strictly only to particles isolated from the bounding surfaces of the fluid. However, Svedberg and Rinde¹³⁴ have shown that for the purposes of measurement use can be made of a small sector-shaped cell which has two flat walls oriented at right angles to the axis of rotation and two others which, if extended, would intersect along the axis. Particles originally close to any of these walls continue during sedimentation to pursue an average course parallel to the wall, so that their radial movement proceeds just as if the bounding surfaces were further removed. However, with the passage of time the concentration of particles does progressively increase near the bottom of the cell and decrease at the top; but if the centrifugal force is sufficiently high, measurements of rate can still be made directly, as will be shown. The particles originally at the top or inner surface of the fluid migrate together, forming a "rear line of march," or moving boundary, which demarcates the supernatant fluid and sedimenting solute. The sedimentation rate is determined by measuring the position of this boundary at

intervals and using the integrated form of $\frac{dx}{dt} \left(\frac{1}{\omega^2 x} \right)$, i.e., $\frac{\ln x_2 - \ln x_1}{\omega^2(t_2 - t_1)}$

to obtain a mean value for s . Generally the boundary becomes progressively less well defined with time because of a superimposed diffusion of particles across the boundary. However, the position which the boundary would have had in the absence of diffusion is simply the level at which the concentration is one-half that in the lower, unaffected sections. When the rate of sedimentation is rapid enough in comparison to the diffusion process, there exists for some time, between the diffuse boundary and the section of the cell in which the particles are accumulating against the wall, a region in which the concentration is nearly uniform throughout (see Fig. 1). The concentration in this region decreases at a steady rate during a constant-speed centrifugation, because of diverging radial movements of the particles and because of the fact that the centrifugal force, and consequently the speed of migration, increases with the distance from the axis of rotation. The relation between this concentration C_t at any time, t , and the original concentration C_0 has been shown by Svedberg and Rinde¹³⁴ to be given by:

$$C_t = C_0 \frac{x_0^2}{x_t} \quad (9)$$

where x_0 and x_t are the respective radial distances of the meniscus and the boundary at time t .

If sedimentation is allowed to progress for a sufficiently long time, usually at a rotational speed considerably lower than that used for the sedimentation velocity method, a state of equilibrium is reached in which the tendency of the particles to sediment is exactly counterbalanced by their tendency to diffuse back into the medium. The molecular weight can then be determined by comparing the concentrations C_1 and C_2 of particles at two radial distances x_1 and x_2 . The formula for the

sedimentation equilibrium method as originally given by Svedberg,¹²¹ and as later proved thermodynamically by Tiselius,¹⁴⁰ is:

$$M = \frac{2RT \ln (C_2/C_1)}{\left(1 - \frac{\rho}{\sigma}\right) \omega^2 (x_2^2 - x_1^2)} \quad (10)$$

With proteins, for example, several days of continuous centrifugation are generally required before the concentration distribution becomes sufficiently constant for the equilibrium formula to be applied. An extension of the mathematical work

FIGURE 1. Sedimentation of monodisperse hemocyanin in the serum of *Limulus polyphemus*, as shown by the absorption method. Speed, 18,000 rpm; interval between photographs, 15 min; illumination, 3650 (Å) line of mercury; cell thickness, 3 mm; approximate concentration, 1.45 per cent.

of Archibald⁸ in obtaining solutions for the general differential equations of sedimentation might permit direct determinations of M with considerably shorter runs. The question of sedimentation in fluid columns which are either not convection-free or not sector-shaped is discussed later in this article.

Density, Shape, Hydration, and Electrical Charge of Particles, and Their Influence on Sedimentation

In the equations given for the determination of molecular weight or particle size it has been assumed, as already stated, that the particles are electrically neutral with respect to the medium, *i.e.*, that they are not electrostatically attracted and influenced by smaller diffusible ions which sediment slower and diffuse faster. However, Tiselius¹⁴¹ has shown that where electrical dissociation is present, the effect on the sedimentation rate of the principal particle can be rendered negligible by the addition of sufficient non-sedimenting electrolyte. About 0.2*M* sodium chloride is usually used to repress this Donnan effect.

Of the several quantities which enter into the computation of molecular weight from sedimentation data, the density of the particles is the one which has aroused the greatest uncertainty because it does not lend itself readily to direct measurement. The density of dried or crystallized material can be determined by measuring with a pycnometer the volume displaced by a known weight of substance. However, because of the possibility of hydration there is considerable doubt as to whether this represents the effective density of the particles sedimenting in a centrifugal field.

This problem has been treated mathematically by Lamm⁵⁵ and Kraemer,⁵³ and was recently discussed in simple physical terms by the author.⁵⁹ It has been found theoretically that only inappreciable error will generally be produced by unknown amounts of hydration or solvation when molecular weights are computed by either Equation 5 or Equation 10, even though σ is taken for unhydrated particles. Specifically, in dilute solutions the proportional error in a determination is $(Z - 1)$, where Z is simply the ratio between the true weight of a mole and the true weight increased by the difference between the weight of the bound material and the weight of an equal volume of the suspending medium. The reason for this relationship is that hydration changes the net centrifugal force acting on a particle only slightly, and increases the frictional coefficient equally in both sedimentation and diffusion. It should be noted that the molecular weight determined by either Equation 5 or Equation 10 is, then, the molecular weight of particles in such a state that their density is the same as that which characterizes the particulate material when the weight of a sample is determined.

When the diffusion constant D and the sedimentation rate s are known for the same temperature T , the values of M , f , and f_0 can be computed from the equations given above. The expression f_0 represents the minimum possible frictional coefficient, *i.e.*, that which particles having the given sedimentation rate would have if they were unsolvated and spherically shaped. The frictional constant is represented by f/f_0 which always has a value equal to or greater than unity. Most naturally occurring monodisperse proteins already studied appear to have constants considerably below 2. In the case of viruses particularly, however, values as high as 2.8 may be obtained.³⁶

Frictional constants greater than unity can be caused by solvation or by lack of spherical symmetry. Usually both factors are present. Adair and Adair¹ have shown several proteins to be hydrated in amounts ranging from 14 to 20 per cent. With some of the larger viruses there is some evidence that the values may be somewhat higher.¹¹² When the frictional constant has been corrected for an assumed or measured degree of solvation by recomputation with properly adjusted values for σ and M , it is possible to gain some idea of the particle shape by the use of equations obtained from the works of Herzog, Illig, and Kudar⁴⁷ and of Perrin⁸⁴ (see also Ref. 133). These equations relate frictional constants with axial ratios for particles assumed to be either oblong or oblate ellipsoids. Observations on the double refraction produced by streaming may give information as to whether the particles are oblong or oblate, and to what extent. Axial ratios of many "globular" proteins are in the neighborhood of 4,⁸⁰ while values of the order of 40 have been found for some viruses.³⁶ Asymmetries may also be investigated by experiments based on measurements of viscosity or dielectric constant.⁸⁰

The density of most proteins in the unhydrated state is very close to 1.33 gm/cc,¹³³ although for thymonucleohistone, as an example, values have been reported ranging from 1.41¹⁰⁴ to 1.50.¹⁰⁰ Some large viruses have been estimated to have hydrated densities of about 1.16 and unhydrated densities near 1.25 to 1.30.¹¹² In certain cases, some idea of the hydrated density can be obtained by ultracentrifugation in media of various densities.¹¹²

From these considerations, it will be seen that Equation 8 can be used directly without supplementary information to determine from a measured sedimentation rate the minimum possible values for the volume and mass of the sedimenting particles. In the case of proteins, even the value of σ may be assumed with some assurance of a fair approximation.

Optical Ultracentrifuges of Svedberg and Associates

In order to obtain higher rotational speeds for sedimentation velocity measurements, Svedberg and Lysholm¹³¹ in 1927 substituted an oil drive for the electric

drive of the centrifuge. In the present improved model,^{29, 133} the steel rotor is driven by oil under pressure and rotates in a reduced atmosphere of hydrogen gas. The sector-shaped cell (see Fig. 2) generally accommodates a column of solution about 16 mm long and is spun in the rotor at speeds up to approximately 70,000 rpm. Smaller rotors with shorter columns have been run at much higher speeds but have been found less efficient for general purposes.¹³³ The thickness of the sector-shaped

FIGURE 2. Photograph of transparent cell used in ultracentrifuges of the vacuum type. Diam. of cell, 25.4 mm; capacity, 0.6 cc; thickness of solution column in direction of light path, 1 cm. Quartz windows permit passage of ultraviolet light. Evaporation through the small filling hole is prevented by a rubber gasket and a screw plug.

solution column parallel to the axis of rotation is usually less than 12 mm, and the average width is only a few millimeters. The center of the cell is 65 mm from the axis of rotation, which is horizontal. The cell is provided with plane-parallel quartz windows which make it possible to direct light rays through the revolving solution in a direction parallel to the axis of rotation. Light passing through openings in a counterbalance or dummy cell at radial levels above or below the solution column is unaffected by the sedimentation and furnishes a convenient reference (see Fig. 1).

In 1929 Svedberg and Sjögren¹³⁵ improved the early low-speed electrical ultracentrifuge used for equilibrium measurements by substituting a direct motor drive for the gear drive.^{124, 133} The motor is of a self-balancing type used for spinning viscose thread in the artificial silk industry (Siemens, Berlin). It is fed with a three-phase A. C. current of variable frequency from a special generator and has a short-circuited squirrel-cage rotor, moving in ball bearings. The 15-cm rotor spins in an atmosphere of hydrogen. The transparent cell and counterbalance are of the same general character as those used with the oil-driven ultracentrifuge. Speeds up to about 20,000 rpm can be employed.

Optical Ultracentrifuges of the Vacuum Type

Although the Svedberg ultracentrifuges have served their intended purpose admirably, they are comparatively complicated and too expensive to be of service to many investigators. Within the past decade there have been developed considerably simpler ultracentrifuges of the so-called vacuum type, which can spin rotors of desirable dimensions under experimentally favorable conditions. The available speed is limited only by the strength of the material from which the rotor is made. It has been the practice to use easily machineable Duralumin in preference to the special steels employed in the oil-driven ultracentrifuge. The resolving power, *i.e.*, the ability to separate materials with sedimentation rates close together, is consequently slightly less than that obtained with the Svedberg machine,¹³³ but is considered close enough

to the practical limit not to warrant more expensive rotors for general purposes.

The first arrangement for spinning large rotors at high speed in a vacuum was described by Pickels and Beams⁹⁵ in 1935. A drawing from the original paper is reproduced in Fig. 3. From a small cone-shaped, air-driven and air-supported rotor

FIGURE 3. Drawing of first high-speed centrifuge of the vacuum type (Ref. 95). The turbine is supported and driven by compressed air. The motion is transmitted to the large rotor through a length of piano wire. Absence of air friction against the large rotor prevents heating and permits practical attainment of high speeds.

of the "spinning top" variety described later in this article, a length of straightened piano wire extended downward through an oil gland into a vacuum chamber and was there fastened to a larger rotor. This wire served as a drive shaft. With almost all the air resistance on the main rotor eliminated and with so little friction offered by the guiding bearings, high speeds could be obtained with little driving energy and without appreciable frictional heating. This was an important circumstance in the avoidance of thermal gradients which can cause convection currents within a liquid being centrifuged.

A little later Beams and Pickels¹⁶ reported improvements in the apparatus and a successful sedimentation of hemoglobin. Adaptations were made with larger rotors by Biscoe, Pickels and Wyckoff, and they conducted a series of tests with circular rotors of the lighter alloys to ascertain what speeds could be safely tolerated.^{26, 27} Bauer and Pickels^{6, 7} introduced many refinements, including an independent air bearing, a system of decelerating by reversed air jets, and particularly an oval-shaped rotor (see Fig. 4) capable of withstanding considerably higher rotational speeds.

The sedimentation of egg albumin at 60,000 rpm was demonstrated. A more dependable air bearing was described in 1938 by the author.⁸⁸ References to improvements and alternative arrangements described by Beams, Hoxton, Chiles, and other investigators are listed in the subject index.

An ultracentrifuge of the modified Bauer-Pickels type^{7, 88} has given consistently satisfactory service in our laboratory for several years. In Fig. 5 is shown a high-speed, vacuum-type centrifuge with the protective steel cylinder of the vacuum

FIGURE 4. Oval-shaped Duralumin rotor of vacuum-type ultracentrifuge with cell and counterbalance shown in position. Maximum diameter of rotor is 18 cm. It withstands routine operation at 60,000 rpm, with an average centrifugal force in the cell 260,000 times that of gravity.

chamber removed. The driving mechanism is the "turret" type described by the author.⁸⁸ The rotor shown is designed for the concentration of biological material in inclined tubes. For ultracentrifugation work a Duralumin rotor such as that in Fig. 4 is used. Its maximum diameter is 18 cm. Rubber gaskets form vacuum-tight joints between the cylinder and the top and bottom steel plates of the chamber. The steel drive shaft is $\frac{1}{40}$ inch in diameter. Its flexibility permits the rotor to be self-balancing. Arrangements, not visible, are provided for collecting small amounts of oil passing through the main guide bearings. The cell⁹² (see Fig. 2) accommodates a fluid column of 1.5 cm maximum length (radially to rotor) and 1 cm deep. Two sets of windows are provided in the top and bottom plates so that two beams of light can be directed vertically through the revolving cell for the purposes of photographing the sedimentation by two different optical methods to be described later. Front-surfaced mirrors inclined at 45° are arranged in line with the windows at a convenient distance above and below the centrifuge so that the camera and illuminating systems can be horizontal. With an air pressure of 70 lbs/in.² the rotor can be accelerated to or decelerated from 60,000 rpm in about 13 minutes. At this speed the average centrif-

ugal force in the cell is 260,000 times gravity. It can be maintained at this speed with a pressure of 22 lbs/in² and a flow of 12 cubic feet of free air per minute. The temperature of the rotor rises less than 1° C per hour when a good vacuum is maintained. The speed is kept constant with little trouble when a system of air-pressure regulators is employed.⁷ The speed can be measured by a variety of stroboscopic arrangements, although a comparatively inexpensive instrument such as the Strobotac (General Radio Co.) is well suited for the purpose, especially when multiples of the A. C. line frequency are used.

FIGURE 5. Photograph of a high-speed angle centrifuge of the vacuum type, with the cylindrical section of the steel vacuum chamber shown removed for the purpose of illustration. The turbine is driven and supported by compressed air. Rotors similar to the 20 cm one shown can be operated near 50,000 rpm. For the ultracentrifuge, top and bottom plates of the vacuum chamber are provided with windows to permit the passage of a light beam vertically through the revolving cell.

Beams and Black¹² and later Skarstrom and Beams¹¹ published descriptions of a high-speed electrical drive which can be substituted for the air drive. The weight of the rotating elements is supported magnetically. An elaborate vacuum-tube oscillator circuit is employed to supply a regulated electrical frequency to a small high-speed induction motor. Remarkably constant speeds can be maintained automatically with this machine. Apparently it is not as practical as the air drive for producing very rapid accelerations. Beams¹¹ has also reported a method for increasing the resolving power of an ultracentrifuge by displacing the solution column with more fluid progressively during centrifugation.

Optical Methods for Measuring Sedimentation

All the earlier sedimentation studies conducted by Svedberg and his collaborators were based on the light absorption method first described by Svedberg and Rinde.¹³⁴ Light of some suitable wave length which is absorbed by the sedimenting solute, but

not appreciably by the solvent, is directed through the cell. Filtered ultraviolet light from a mercury arc is usually employed for protein solutions. With visible light passing through a hemoglobin solution within the revolving cell, for example, the unaided eye sees a bright red annular band extending about the axis of rotation. The meniscus of the fluid appears as a fine line with the same center of curvature. The sedimenting boundary demarcating the clear supernatant and the solution is also concentric about the axis. To obtain a record of the sedimentation, it is necessary to photograph at intervals only a narrow cross-sectional strip of the total annular band of light. A camera of long focal length (100 cm) is used, in order to avoid errors of parallax and to give good focusing for all depths in the cell. A typical sedimentation of a large homogeneous protein is illustrated by the series of photographs in Fig. 1. An absorption photograph showing two sedimenting components is shown in Fig. 6.

FIGURE 6. Sedimentation photographs illustrating correlation between absorption method and refractive index method. Material, polydisperse hemocyanin in diluted serum of *Limulus polyphemus*; speed 16,200 rpm; time 2.26 hrs after full speed; cell thickness, 1 cm; total protein concentration, 0.41 per cent.

Other optical methods which have to a great extent superseded the absorption method are based on the detection or measurement of deviations suffered by light rays passing through regions of refractive index gradient such as exist at sedimenting boundaries. The basis from which these methods have stemmed can be traced to the fundamental work of Weiner,¹⁴⁸ published in 1893. Lamm^{56, 57} was the first to apply a refractive index method to the measurement of sedimentation. His so-called scale method can probably still be made subject to the fewest optical errors of any refractive index methods. It involves a great deal of tedious measurement and computation, and increasing attention is being given to other optical arrangements. Tiselius, Pedersen, and Eriksson-Quensel¹⁴² have applied the principle of Toepler's schlieren method to the ultracentrifuge. A sedimentation boundary is located immediately by the appearance on the camera screen of a dark band at the region of steep concentration gradient. Concentration of a component cannot be measured in a practical manner, as with the scale method.

The cylindrical lens methods which have proved so useful originate in the work of Thovert.¹³⁹ Philpot⁸⁵ combined certain features of the Thovert method and the Toepler schlieren method to obtain the first automatically recorded refractive index curves with the ultracentrifuge. Andersson² later described an alternative arrange-

ment. Svensson^{136, 137} modified Philpot's method for use with the Tiselius electrophoresis apparatus and made an extensive study of various theoretical aspects of the method. For example, he compared the pattern obtained with different inclined slits with those obtained by a simple inclined knife edge as used by Philpot. As with the absorption system, lenses having focal lengths of the order of 100 cm are used so that all depths within the cell are in focus.

Experience in our laboratory with a modification of Svensson's method has indicated that even with comparatively inexpensive optical parts a precision of measurement can be attained which is quite sufficient in view of the many minor uncertainties involved in the ultracentrifugal method. Special tests have shown that deviations of light produced at any level of the cell, at least deviations up to .02 radian, can be registered at the photographic plate with an error of less than 1 per cent, and that for all deviations in this range the image positions of every level in the cell can be produced with an accuracy of less than 1 per cent of the total cell height.

A schematic representation of the optical principles involved is given in the perspective drawing of Fig. 7. A camera lens is placed so as to form on a screen

FIGURE 7. Perspective schematic drawing illustrating the working principle of a refractive-index method employing a cylindrical lens.

the images A' , B' , C' of the three small holes A , B , and C in a thin diaphragm. A condensing lens is placed so as to focus the image of a horizontal line source on the front surface of the camera lens. Limit consideration to those light rays which pass through the small holes. It can be seen that the light eventually constituting each of the images A' , B' , C' consists of rays which alternately diverge and converge in accordance with simple optical principles. Each set of rays may be thought of as making up a "light sheet" that varies in width but is always parallel to the horizontal line source. If the light sheet diverging from A toward the camera lens were deviated downward from the normal course at A , as indicated by the dotted lines, it would nevertheless converge at A' by reason of the fact that the camera lens is

focused to produce such a result. An analogy holds for all other images. Suppose that a cylindrical lens with vertical axis is added to the system in such a position that a point light source at the front surface of the camera lens would be focused as a vertical line image at the screen. The effect of this lens on each of the original light sheets will be to converge it prematurely, so that it again diverges and forms a horizontal line image $A_1' A_2' A_3'$ on the screen instead of a point image. The vertical positions of the images are not altered by the cylindrical lens. A downward deviation (dotted lines) of the sheet at A would not alter the position of the line image. Suppose that over the front surface of the camera lens is placed a mask provided with a narrow inclined slit. It can be seen that of the undeviated rays through A, only the central one is now able to pass through the camera lens and reach the screen, where it will appear as a point of light A_2' , as contrasted to the previous horizontal line image $A_1' A_2' A_3'$. Since the undeviated light sheets through A, B, and C all converge in a common image of the light source at the mask, it follows that B and C will also be represented at the screen, when there is no deviation at the diaphragm, by light points B_2' and C_2' , which are situated along a central vertical line passing through A_2' . However, if the light sheet from A, for example, is deviated downward sufficiently from its normal course, then only the ray at one edge of the light sheet will pass through the camera lens, and the light point corresponding to A will appear on the screen at A_3' . The horizontal distance by which any light point will be displaced from the central line $C_2' A_2'$ is directly proportional to the downward displacement suffered by the corresponding light sheet at the diaphragm. The same holds true for light coming from B or from C, and thus the system is capable of translating a vertical deviation of light into a horizontal displacement of a light point on the screen without altering the point's vertical height which is characteristic of a certain level in the cell.

Consideration will show that the action of the system is not altered by substituting narrow horizontal slits for the holes A, B, and C. For any given deviation of a light sheet, more rays will pass through the camera lens, but since they do pass through at the same point the cylindrical lens converges them into a point focus again at the screen. Now suppose that a cell containing an immobilized sedimentation boundary is substituted for the diaphragm in such a way that the maximum refractive index gradient, *i.e.*, the center of the boundary, is in the position B. The corresponding point B' will be the one suffering the maximum horizontal displacement from the center line on the screen. Light coming through the cell below and above the boundary, as at A, is not deviated and the corresponding light points fall on the center line. Displacements of light points corresponding to successive positions within the boundary are proportional to the respective refractive index gradients, with the result that the light points form a smooth continuous curve on the screen. The peak of the curve, if symmetrical, determines the position of the boundary; the area between the center line and the curve is proportional to the concentration of the material forming the boundary, assuming it is the only source of refractive gradients. With the ultracentrifuge there are extraneous gradients due to hydrostatic compression and distortion of the cell, and a curve incorporating these alone and called the base line must be obtained. The magnitude of this effect can be seen in the photographs of Fig. 9. If heavy salt ions are present in sufficient strength in the medium, they too produce gradients which must be taken into account by making separate ultracentrifugation runs with the medium alone.¹³³ In applying the method to the centrifuge it is important to limit the light passing through the revolving cell to a zone having a width of not more than a few millimeters in a tangential direction.

In our laboratory, the substitution of an opaque strip for the inclined open slit has produced certain advantages. In place of a line of light as described above, a dark band against a bright background indicates deviations of light at various

FIGURE 8. Pictures taken during the experiment illustrated in Fig. 1 and showing sedimentation in the same hemocyanin solution, as recorded by the refractive-index method.

FIGURE 9. Photographs illustrating the gradients of refractive index introduced in a water-filled ultracentrifuge cell at high speed by hydrostatic compression and distortion of the cell.

depths in the cell. Measurements are taken from both edges of this band and averaged.

The photographs of Fig. 8 illustrate an application of the refractive index method employing a cylindrical lens. These were obtained during the same run as were those of Fig. 1. Fig. 6 is an example of the simultaneous sedimentation of two protein components and shows the correlation existing between photographs taken of the same material at the same time by the refractive index and absorption methods.

Experimental Considerations

For most cases the refractive index method is preferable to the absorption method, particularly in the study of mixtures and where it is desired to determine the absolute or relative concentrations of several components. There is a considerably greater proportional variation in the absorption coefficients of proteins in the ultraviolet region, for example, than there is in their specific refractive indices in the visible region.⁶⁹ As a matter of fact, good approximations of the concentrations of protein components of unknown optical properties can nearly always be made with the refractive index method. It is also an advantage to be able to observe the sedimentation on the screen with visible light during sedimentation. Furthermore, it is more expensive and less convenient to work with ultraviolet light, which requires quartz optical parts.

A good refractive index system is subject to fewer and less serious errors than is an absorption system. The pictures shown in Fig. 1 represent an unusually sharp boundary of a fairly concentrated, slowly diffusing material. Measurements can be made directly from the photographs. In actual practice, however, boundaries of smaller, more common proteins are more diffuse, such as those shown in Fig. 6. To analyze absorption photographs, it is then necessary to employ a microphotometer which will measure the photographic density of the plate at all levels in the cell picture. Results obtained must then be translated into measurements of concentration. The analysis is subject to all the usual photographic errors, as has been pointed out by Pedersen.¹³³ The apparent position of a diffuse boundary and the apparent concentration distribution throughout the cell can be greatly altered by photographic overexposure or underexposure and also by the use of a highly absorbing preparation in the cell. It is imperative to use monochromatic light of high purity and to illuminate the cell uniformly.

In some cases, however, the absorption method is to be preferred. For example, Pickels and Bauer⁹⁴ found that the virus of yellow fever in infected monkey serum showed a high differential absorption in the upper ultraviolet region, and they were able to study, by absorption, sedimentation boundaries which could not be detected with the refractive index system. Since the precision of the refractive method depends on the magnitude of the concentration gradients rather than on the concentration itself, the absorption method is sometimes more applicable with unusually ill-defined boundaries or with very inhomogeneous preparations. Infrared light can be employed in cases where visible light is too strongly absorbed by the solution.¹⁴⁵

The sedimentation equilibrium method requires several days of continuous operation and is most useful for the investigation of purified preparations which are known to be homogeneous, since in a mixture, the contributions of several species to the distribution of total concentration are not easily differentiated.¹³³ The sedimentation velocity method, on the other hand, is ideal for the study of mixtures, since an individual boundary is obtained for each species whose rate is sufficiently different from that of the other components. The method is of great assistance in judging the purity and homogeneity or monodispersity of a sedimentable material. For most proteins, an experiment can be completed within a few hours. Runs should be made with several concentrations of material, and the results extrapolated to zero concen-

tration to determine the true sedimentation constant. It is known that in mixtures of proteins, for example, there is often an interaction between the different proteins, and the possibility of this effect must be taken into account. The problem has been discussed by Pedersen⁸³ and by Lundgren and Williams.⁶⁴

In the earlier sedimentation velocity experiments of Svedberg determinations of the diffusion constant were attempted upon the material under study while it was sedimenting in the ultracentrifuge. An argument in favor of the procedure was that the environmental conditions were identical for both sedimentation and diffusion measurements. In later years it was found that the diffusion values obtained in this manner were not very reliable. Probable reasons for this have recently been discussed by the author.⁸⁹ Concentration is an important factor. In the photographs of Figs. 1 and 8, for example, the boundary shows with increasing time an increase in spread which is only a small proportion of the amount to be expected from measured values of the diffusion constant. The contrast with the spread of the more dilute boundaries in Fig. 6 is at once evident. The author⁸⁹ has tested a new method by which it is possible to make good diffusion measurements in the ultracentrifuge, even with mixtures when they give resolvable boundaries in the centrifugal field.

It is important to know accurately the temperature of the solution revolving in the ultracentrifuge so that its viscosity can be compared with that of the standard medium. With the vacuum-type ultracentrifuge, the temperature of the rotor is taken by thermocouple before and after each run. No appreciable error is introduced by taking the average of these readings as the temperature of the run, which is usually very near room temperature. For the investigation of materials which exhibit excessive instability under such conditions, Rothen¹⁰⁰ has surrounded his air-driven ultracentrifuge rotor with stationary refrigerated metal surfaces which permit him to maintain the material under study near 0° C. Hydrogen at a reduced pressure of about 0.1 mm of mercury furnishes the thermal conduction and permits the maintenance of a constant rotor temperature.

However, the maintenance of a constant *average* temperature within the rotor is of no consequence within itself in preventing disturbing convection currents within the solution. The principal potential sources of convection currents are temperature gradients which must exist within the cell to insure the passage of heat from the sections of the rotor exposed to the greatest proportion of frictional resistance to those exposed to smaller amounts, *i.e.*, from the faster moving periphery to the central zone. A rotor spinning in a vacuum represents the ideal case as far as convection-free sedimentation is concerned. It should be remembered that the convection action is enormously magnified by high centrifugal force and can interfere seriously with the sedimentation of small particles.⁹³ Beams⁹ and the author⁸⁹ have shown that the compressional gradient produced by the centrifugal field is of little assistance in inhibiting convection. A method of testing for thermal convection currents has been suggested in a recent article.⁹³ Slight misalignments of the ultracentrifuge cell can also cause convective disturbances.⁹²

While there is some uncertainty as to whether the viscosity of the solvent rather than that of the solution represents the correct value for use in the Svedberg formula, the problem is of little consequence if rates are extrapolated to zero concentration.

Typical Applications of the Optical Ultracentrifuge

Svedberg and his collaborators have investigated a great number of high molecular weight substances, especially proteins,¹²⁵ with the electrically driven and oil driven ultracentrifuges. Although the newer ultracentrifuges of the vacuum type have been employed for a comparable variety of purposes, their principal use to date appears to have centered around the study of filterable viruses. A complete bibliography for the whole field of ultracentrifugation will be found elsewhere¹³³ and the references to many typical experiments will be found listed in the subject index of

this article. To mention a few: McFarlane⁶⁰⁻⁷³ has made an extensive study of the components of normal and pathological sera; Svedberg and Hedenius¹³⁰ have compiled a great deal of information regarding the respiratory proteins; studies have been made by others to determine the effects on various proteins of desiccation,³⁰ suspension in heavy water,¹²⁸ association with other proteins,⁸³ subjection to ultraviolet light and x-rays,^{127, 102} and treatment with x-rays.¹⁰² That molecular weights as low as 14,000 can be determined conveniently by the sedimentation velocity method with the vacuum-type ultracentrifuge is illustrated by the work of Rothen⁹⁸ with ribonuclease.

Among the viruses which have been studied in the optical ultracentrifuge are bushy stunt virus protein,^{74, 58, 61, 59} the elementary bodies of vaccine virus,^{96, 112} tobacco mosaic virus,^{117, 58} chicken tumor agent,¹¹⁹ the virus of equine encephalomyelitis,¹³⁸ alfalfa mosaic virus,⁶⁰ yellow fever virus,⁹⁴ the virus of mouse encephalomyelitis,³⁶ cucumber virus,⁵² and rabbit papilloma virus.⁷⁹ Published accounts of these investigations describe many interesting experimental data regarding the size, shape, density, and state of dispersion of viruses, as well as their physical reaction to various hydrogen ion concentrations and other agents.

Certain naturally occurring carbohydrates^{25, 129, 38} have been examined in the ultracentrifuge and some have been found by Svedberg and Gralén¹²⁹ to be nearly monodisperse. Pedersen⁸² has applied the sedimentation equilibrium method to the study of such low molecular weight substances as small inorganic salts. Some detergents¹¹⁴ have been found by ultracentrifugal analysis to form large micelles which sediment in the centrifuge. In the case of digitonin, the micelles were found to be quite monodisperse. Further references are given in the subject index of this article to studies of several other materials of special importance, such as antibodies, hormones, etc.

"Spinning Top" Centrifuges

In 1925, only two years after the first comparatively low-speed ultracentrifuge of Svedberg and Nichols was built, Henriot and Huguenard^{45, 46} described a new method for obtaining very high rotational speeds without the use of mechanical bearings. Employing a whirling layer of air issuing under pressure from properly directed jets for both supporting and driving a small cone-shaped rotor only 1.17 cm in diameter, they were able to attain a speed of 660,000 rpm. A few years later the method was confirmed by Beams.⁸ He and his collaborators^{20, 17, 16} introduced many improvements and with a 0.9 cm rotor driven with hydrogen gas were able to reach 1,200,000 rpm.¹⁷ They attempted, with larger rotors, to adapt the air-driven "spinning top" as ultracentrifuges of both the optical and opaque type. An illustration of a "spinning top" taken from one of the original papers¹⁶ is shown in Fig. 10. In 1934, Beams, Pickels, and Weed¹⁷ reported the successful sedimentation of haemoglobin and ascribed earlier failures in this direction to the disturbing action of convection currents caused by temperature gradients through the rotor. They had found that for any degree of sedimentation with molecular particles to be accomplished, the thickness of the solution layer had to be kept very small; *i.e.*, of the order of 0.1 cm or less. From these and other studies by Bauer and Pickels,⁷ it was concluded that the "spinning top" centrifuge was not adequately suited to serve as an ultracentrifuge which would give results comparable in precision with those obtained in the Svedberg machine. Even with arrangements which would counteract the temperature gradients to some extent,¹⁷ it was felt that experimental results would be too unreliable, especially with dilute preparations and thick layers of fluid. These are just the conditions that must be realized for the accurate determination of sedimentation constants with an optical ultracentrifuge. In a recent article,³³ the author has presented experimental evidence regarding the following items: the presence of convection currents in rotors exposed to air resistance but spinning at constant tem-

perature (average); the dependence of such disturbances on the concentration; and the fact that a sharp sedimentation boundary may migrate at an abnormal rate and is itself no proof of convection-free sedimentation.

Also, it was apparent that rotors simulating those of Svedberg in size and providing a theoretically comparable resolving power would be entirely impractical in the form of a "spinning top" because of the enormous driving energy required. These

FIGURE 10. Schematic drawing of a typical "spinning top," which is supported and driven by jets of compressed air (see Ref. 16). Rotors are usually a few centimeters in diameter and available speeds are of the order of 100,000 rpm.

considerations led to the development of the vacuum-type ultracentrifuge which has been described earlier in the article.

McBain and O'Sullivan^{67, 68} and a few other investigators¹⁰¹ have continued to use the "spinning top" as an ultracentrifuge and have reported several successful sedimentations, using various improved forms of the apparatus. However, the reliability of some of their results has been questioned by Williams and Watson.¹⁴⁹

In certain instances where precise quantitative measurement has not been the principal consideration, the "spinning top" has been employed to great advantage. For example, McIntosh⁷⁵ has successfully concentrated bacteriophage and fowl sarcoma virus, and Gratia and Goreczky³⁹ have demonstrated the sedimentation of immune hemolysin. Rotors with diameters as large as 20 cm have been used for preparative purposes by Bauer and the author.⁵ Some very interesting observations have been made by Beams and King²¹ and by Guyer and Claus⁴⁰ regarding the effects of high centrifugal force on biological cells. Harvey^{41, 42} employed the "spinning top" for similar purposes even earlier than these investigators, and, in addition, he perfected an optical arrangement whereby an individual cell could be microscopically observed while it was being centrifuged. An alternative arrangement has been described by the author.⁸⁶

High-Speed Angle Centrifuges for Purification and Concentration of Molecular Particles

In the ordinary preparative or low-speed laboratory centrifuge, freely swinging buckets carry tubes or cylindrical containers filled with fluid. For centrifugation at high speeds, it is desirable and usually necessary to provide fixed holes or receptacles for the tubes. This arrangement makes it possible to design rotors with the mechanical strength required for high speeds and to furnish the rotors with a symmetrical surface, with respect to the axis of rotation, which will minimize the resistance and consequent heating caused by the friction of the surrounding air. The tube holes are usually arranged at some angle between 20° to 45° to the axis of rotation for several reasons: a partially filled tube will not overflow either while the centrifuge is spinning or while it is at rest; the greatest number of tubes can be accommodated and a rotor

of given capacity can be made mechanically stronger when comparatively small angles are employed;⁹¹ and such angles are known to be favorable to the rapid deposition of sedimenting material.^{150, 151, 93}

The scheme of inclined tubes is used in certain motor-driven commercially available centrifuges, principally the comparatively slow-speed Swedish Angle centrifuge and the International centrifuge with high-speed attachment. The latter involves a step-up pulley-belt system which can be operated at about 18,000 rpm, but unfortunately the size and capacity of the rotor furnished with this equipment are comparatively small. Claude³³ has employed the apparatus for the sedimentation of chick tumor extracts and haemocyanin. The author has published descriptions⁹⁰ of a simply constructed angle centrifuge with direct electric motor drive. Interchangeable rotors fit directly on the shaft of a flexibly mounted universal motor which is commercially available. Fig. 11 shows a photograph of the apparatus. The rotor il-

FIGURE 11. High-speed preparative angle centrifuge of the type designed by the author (see Ref. 90). Rotor fits directly on shaft of universal electric motor, which is flexibly mounted. For rotor illustrated: diameter, 20 cm; number of tubes, 18; capacity, 166 cc; speed, 18,000 rpm; maximum centrifugal force on fluid, 34,800 times gravity. Other rotors accommodate up to 610 cc of liquid.

lustrated is almost 8 inches in diameter, accommodates 166 cc of fluid, and spins at 18,000 rpm with an applied potential of 180 volts or at 12,500 rpm with a potential of 115 volts. The original article⁹⁰ gives specifications and operational data for rotors having diameters ranging from 7 to 10¼ inches and capacities ranging from 112 to 610 cc of fluid. The temperature of a rotor reaches a steady value a few degrees above the temperature of the surrounding air. The apparatus can be operated inside a refrigerator when it is desirable to keep the rotor cold. A study of the sedimentation process in these centrifuges has been made by the author.⁹³ In common with all centrifuges which spin in the open air, they are subject to convective disturbances

but have been found convenient for rapid clarification and for the concentration and purification of very large molecules. Sedimentation boundaries^{33, 93} of high molecular homogeneous materials can be detected in tubes which have been centrifuged in open-air machines when the concentration is sufficiently high. Work of the author⁹³ has shown that even with low concentrations, boundaries can be obtained by originally providing the solution column with a synthetic density gradient formed with sucrose or some other nonsedimenting solute. Such a gradient counteracts the effects of the temperature gradient which tends to produce convection.

The first high-speed angle centrifuge to be spun in a vacuum, and thus rendered convection free, was described in 1936 by Bauer and Pickels.⁶ An improved form of this apparatus is shown in Fig. 5, with the cylinder of the vacuum chamber removed for the purposes of illustration. The arrangement of the inclined tube holes is similar to that shown in Fig. 11. Since glass tubes do not withstand high centrifugal forces without cracking, celluloid tubes of the variety introduced by Bauer and Pickels⁵ are used. For work which must be performed under sterile conditions, tubes with screw caps are convenient.⁹¹ They can be sterilized with ultraviolet light. The air drive illustrated in Fig. 5 is of the improved "turret" type which has been described by the author⁸⁸ and which is still used routinely. Except for the lid, the rotor is machined from a solid piece of Duralumin and is 8 inches in diameter. A rubber gasket forms a vacuum-tight joint between the rotor proper and the lid, which is held in place by six screws. Stress analyses for several different rotor designs by the author⁹¹ have indicated that a correctly proportioned rotor accommodating several hundred cubic centimeters of fluid can be run at speeds as high as 50,000 rpm with attendant centrifugal forces of the order of 200,000 times gravity.

Alternative air drives for the vacuum type angle centrifuge have been described by other research workers, notably Beams, Linke, and Sommer.¹⁵ Rawson, Scherp, and Lindquist⁹⁷ have employed successfully as a substitute for the air drive a commercially available, electrically operated "lathe grinder" drive. They report the attainment of speeds as high as 44,000 rpm. Masket⁶⁵ has described a simple arrangement for plugging each hole and its celluloid tube individually, so that the tubes can be more completely filled and inclined at smaller angles to the axis of rotation. Wyckoff and Lagsdin^{150, 151} have investigated experimentally the efficiency of tubes inclined at various angles and have shown that small angles are best for concentrating molecular particles. The author⁹³ has investigated the sedimentation process in the vacuum type angle centrifuge with special reference to the following: the detection and measurement of partially sedimented boundaries; methods of improving the definition of such boundaries by the use of synthetic density gradients; the effects of convection caused by deceleration forces acting on the fluid; the influence of concentration; the effect of changing the tubes' dimensions; the correlation of results with those obtained in the electrical centrifuge⁹⁰ and in the ultracentrifuge;⁷ and the reasons why small numbers of particles always remain in the supernatant fluid.

Since the concentration of yellow fever virus⁶ with the first angle centrifuge of the vacuum type, similar machines have been used extensively for the purification and concentration of viruses and other small particles of biological significance. For example, Stanley¹¹⁶ has concentrated the tomato bushy stunt virus, and Beard, Bryan, and Wyckoff²² have isolated the rabbit papilloma virus. Purification through differential centrifugation involves no chemical treatment of the material under study and often offers a decided advantage in this respect.

High-Speed Centrifuges of Other Types

For research purposes, angle centrifuges are greatly favored for preparative work because of the convenient manner in which the material under study can be handled and the sediment collected. However, Schlesinger,¹⁰³ for example, has used hollow closed cylinders which are spun about their axes of radial symmetry. More recently,

McIntosh and Selbie⁷⁶ have described an adaptation of the Sharples air-driven tubular centrifuge. The cylinder of the centrifuge is about 5 cm in diameter and is usually operated at 40,000 rpm. The centrifuge is of the continuous-flow type and 15 to 20 cc are passed through the rotating cylinder per minute. Successful concentrations of several viruses, bacteria, and bacteriophage have been reported. The apparent absence of marked convection is probably due to the fact that the layer of fluid within the centrifuge is only about 0.55 mm thick. Beams, Linke, and Skarstrom¹⁴ have experimented with tubular, continuous-feed centrifuges spinning inside a vacuum chamber. They reported a partial separation of hemoglobin molecules from solution. Other papers^{19, 18} have described the use of similar apparatus for separating gases and gaseous isotopes. The scarcity of reported applications of the tubular vacuum centrifuge in biological research is evidence of the many problems which are peculiar to this type of machine. Its great potential value will probably be realized as further experience is accumulated.

For the estimation of sedimentation rates, several investigators have made use of the "inverted capillary" technique which apparently was originated by Bechhold and Schlesinger.²⁴ For example, Elford and Galloway³⁴ have determined the sedimentation rates of the viruses of vesicular stomatitis and foot and mouth disease. Scott and Elford¹⁰⁵ have similarly studied the virus of lymphocytic choriomeningitis. Their electrically driven centrifuge is an "Ecco Blitz" model of Collatz and runs in the open air at about 15,000 rpm. The material to be studied is placed in small capillaries and the sedimenting particles migrate into a larger reservoir filled with the same material. After centrifugation, the degree of sedimentation is estimated by comparing the average concentration of the liquid in the capillaries with that in the reservoir. The success of the apparatus undoubtedly depends in a large degree upon the inhibition of convection currents due to the small size of the capillaries.

A simple optical ultracentrifuge with a small rotor and cell made of transparent plastic has been described by Stern.¹¹⁸ It rotates about a horizontal axis in mechanical bearings and is driven by air jets impinging at the periphery. The temperature distribution is perhaps somewhat more favorable than with the "spinning top," but the limitations of the two are, in general, the same. Also, there are objections to the use of plastic materials from the standpoints of both optics and mechanical strength.⁹¹

Sampling of Centrifuged Material and Correlation of Specific Properties with Sedimentation Rate

Some idea of the degree of sedimentation experienced by a particular substance under given conditions can be had by comparing the concentration of the sediment with that of the supernatant fluid, using some specific property as a basis of measurement. To relate more accurately the intensity distribution of some specific property with the sedimentation of an optically registered boundary, Tiselius, Pedersen, and Svedberg¹⁴³ have provided the optical ultracentrifuge cell with a porous partition near its center. After a boundary is observed to have passed through the filter, the ultracentrifuge is stopped and the concentrations of the material in the two halves of the cell are compared by chemical or biological tests. Obviously, several experiments with different centrifugation times may be required for a conclusive correlation. It has been found that with the vacuum-type ultracentrifuge, the rotor may be brought to rest and the cell removed without greatly disturbing the appearance of a partially sedimented boundary.⁹⁴ The cell can then be sampled at several successive levels by a simple displacement technique. Also, it can be placed in front of a spectrograph slit and the differential absorption across the boundary measured for different wave lengths. Correlation is more definitely established in a single run when concentrations at several levels can be compared by the different methods.

As shown by studies which the author has made,⁹³ the estimation of sedimentation rate is always hazardous unless a definite sedimenting boundary can be demonstrated.

Fortunately, boundaries can be obtained under certain circumstances with the convenient angle centrifuges.⁹³ Transparent tubes can be removed and photographed to demonstrate the boundary optically. By a technique which Hughes, Pickels, and Horsfall⁴⁹ have described, the fluid columns can be sampled with accuracy at any number of levels. With dilute materials which do not lend themselves to optical measurement, this technique had proven to be far superior to others tried in estimating homogeneity and sedimentation rate. Simple equations have been derived by the author⁹³ which can be used as approximations in determining the size of particles from the degree of sedimentation experienced in an angle centrifuge. The equations are based on the observation that a boundary in an angle centrifuge migrates at roughly the same rate, measured radially, as it does in an ultracentrifuge.

Measurement of the Surface Areas of Finely Divided and Porous Materials by Low-temperature Adsorption Isotherms

P. H. EMMETT

Johns Hopkins University, Baltimore, Md.

The adsorption of gases on solids has been known and studied for many years. In a few instances¹ attempts have been made to utilize chemisorption or physical adsorption measurements in estimating the surface areas of finely divided or porous materials. Such attempts have met with two outstanding difficulties. In the first place, it is often difficult to find suitable adsorbates for chemisorption measurements on the particular solid being studied. Secondly, satisfactory criteria are usually lacking for judging the point on a chemical or physical adsorption isotherm corre-

sponding to the completion of a monolayer. Within the past six years a great deal of work has been done in an endeavor to find a way of utilizing adsorption isotherms for measuring accurately the absolute as well as the relative surface areas of finely divided porous or non-porous solids. A method has been evolved that appears to have much promise and that up to the present has been used in measuring the absolute surface area of metallic Fe,² Ni,³ and Cu³ catalysts; silica gel,³ chromium oxide gels,³ soils,⁴ powdered bacteria,⁵ carbon blacks,⁶ paint pigments,⁶ and a variety of other substances. In the present paper a brief description of the principle and the experimental nature of the method will be presented, together with a few results to illustrate its applicability.

The principle of the method is comparatively simple. If one can select from an experimental adsorption isotherm the volume and hence the number of molecules of some inert gas, such as nitrogen, corresponding to a monolayer, a simple multiplication by the average cross-sectional area of each molecule will yield the absolute surface area of the adsorbent. The accuracy of the method must obviously rest upon (a) the exactness with which the point corresponding to a monolayer of adsorbed molecules can be picked, and (b) the closeness to which one can approximate the average area covered by each adsorbed molecule.

FIGURE 1. Adsorption of Nitrogen on Carbon Blacks at Liquid Nitrogen Temperatures.
1. 3.29 grams of Arrow black
2. 3.09 grams of Micronex
3. 2.95 grams of Wyex
4. 2.86 grams of P-33
5. 0.792 gram of acetylene black
6. 5.50 grams of thermatomic
7. 4.44 grams of Thermax

Early in the experimental work² the point corresponding to a monolayer of adsorbed gas (hereafter designated as "point B") was selected empirically, on the basis of accumulated evidence, as the lower pressure extremity of the long linear portion of the adsorption isotherm (see Figure 1, for example). The experimental evidence that led to the selection of point B on the iron catalysts was threefold. In the first place, the surface area for a given catalyst, as calculated from a series of isotherms

for argon, oxygen, nitrogen, carbon monoxide, carbon dioxide, and butane, showed better agreement if the volume of gas at point B was considered to be a monolayer than if any of the other likely points on the isotherms was chosen. The maximum deviation of the surface area values from the mean calculated from these adsorption isotherms was only about 10 per cent on the iron catalysts. Secondly, the heats of adsorption calculated by the Clapeyron equations from a series of adsorptions at different temperatures showed that the heat of adsorption at point B was intermediate between probable values for first-layer adsorption and for second-layer adsorption. Thus, for the adsorption of a volume of gas 25 per cent greater than at B, a molal heat of adsorption close to that of liquefaction of the gas was obtained, whereas for a volume 25 per cent smaller, the heat of adsorption was at least 50 per cent greater than the heat of liquefaction and was clearly characteristic of adsorption in the first layer. Finally, the chemisorption of a layer of carbon monoxide over the entire surface of the pure iron catalyst required a volume of carbon monoxide approximately equal to the volume of physically adsorbed gas at B on the low-temperature isotherms. These three separate types of evidence combined to convince the author that the volume of gas corresponding to point B on the isotherms was approximately that required for a monolayer.

An excellent confirmation of the selection of point B as the monolayer and a valuable new working tool in using this method of surface area measurements are contained in a recent paper⁹ on the theory of multilayer adsorption such as is apparently being obtained in S-shaped isotherms of the type shown in Figure 1. It is shown that the isotherm can be plotted in such a manner as to yield a straight line whose slope and intercept yield directly the volume of gas required to form a monolayer. The complete equation is

$$\frac{p}{V(p_0 - p)} = \frac{1}{V_m C} + \frac{(C - 1)p}{V_m C p_0} \quad (1)$$

where V is the volume of gas adsorbed at pressure p , at a temperature at which the vapor pressure of the liquefied gas is p_0 ; V_m is the volume of gas in cc required to form a monolayer; and C is a constant related exponentially to the difference between the heat of liquefaction of the adsorbate and its heat of adsorption. It is evident that from the slope and intercept of a plot of $p/V(p_0 - p)$ against p/p_0 both V_m and C can be evaluated.

Application of equation (1) to several hundred isotherms obtained during the last few years shows excellent agreement between the volume of gas adsorbed at point B and the volume V_m . A few examples of the closeness of the agreement are presented in Table 1.

Table 1. Volume of Adsorbed Nitrogen in a Monolayer on Various Adsorbents *

| Absorbent | Volume V_m (ml per g) | Volume at Point B (cm ³ per g) |
|--|----------------------------|--|
| Unpromoted Fe catalyst 973 I | 0.13 | 0.12 |
| Unpromoted Fe catalyst 973 II | 0.29 | 0.27 |
| Fe-Al ₂ O ₃ catalyst 954 | 2.86 | 2.78 |
| Fe-Al ₂ O ₃ catalyst 424 | 2.23 | 2.09 |
| Fe-Al ₂ O ₃ -K ₂ O catalyst 931 | 0.81 | 0.76 |
| Fe-Al ₂ O ₃ catalyst 958 | 0.56 | 0.55 |
| Fe-K ₂ O catalyst 930 | 0.14 | 0.12 |
| Fused Cu catalyst | 0.05 | 0.05 |
| Commercial Cu catalyst | 0.09 | 0.10 |
| Cr ₂ O ₃ gel | 53.3 | 50.5 |
| Cr ₂ O ₃ glower | 6.09 | 6.14 |
| Silica gel | 116.2 | 127.0 |

* The values shown in columns 2 and 3 were obtained from nitrogen adsorption isotherms at about 77° K.

The linearity of the isotherms plotted according to equation (1) extends up to a relative pressure of about 0.35. This is sufficient for evaluating V_m . A typical set of such plots is shown in Figure 2 for the carbon black samples for which the adsorption isotherms were given in Figure 1.

One particular advantage of equation (1) for obtaining V_m arises from the fact that only a few experimental points are needed in the range 0.05 to 0.35 relative pressure, provided the solid is known to yield an S-shaped isotherm. In fact, a single adsorption point at a relative pressure of about 0.3 will, when connected with the origin on such a plot, give a line whose slope usually will differ by less than 5 per cent from that drawn with the help of a number of adsorption points. In practice it has become customary to determine only 3 or 4 experimental points in the relative pressure range below 0.35, since the slope of the straight line so obtained is indistinguishable from that resulting from a larger number of points.

The second factor upon which the absolute values obtained for surface areas will depend is the area occupied by each adsorbed molecule. In a previous publication it has been pointed out that two convenient and reasonable molecular area values are those corresponding to the packing of the molecules in the solidified [Area (S)] and the liquefied adsorbates [Area (L)]. The equation by which the area per molecule has been calculated is

$$\text{Area per molecule} = 4 (.866) \left(\frac{M}{4\sqrt{2} AD} \right)^{\frac{1}{2}} \quad (2)$$

where M is the molecular weight of the adsorbate, A is Avogadro's number and D is the density of the liquefied or solidified gas. The equation assumes close packing of the adsorbed molecules. A list of the areas calculated for the various adsorbate molecules has been published.² It will suffice here to note that the area per molecule calculated from the density of the liquefied adsorbate is about 20 per cent larger than that from the solidified adsorbate. Hence absolute surface area measurements must be regarded as uncertain by at least this amount, though experience has shown that relative areas of materials are reproducible to a few per cent by the adsorption method. Taking 16.2 square Ångströms as the average area occupied by an adsorbed nitrogen molecule as calculated from the density of liquefied nitrogen, one obtains a factor of 4.38 by which to multiply the volume of nitrogen (S.T.P.) in a monolayer on a gram of adsorbent to obtain the surface area in square meters per gram. This constant has been used in the surface area calculations in the present chapter.

Experimental

The detailed experimental procedure for obtaining the adsorption isotherms has been adequately described elsewhere^{10, 1} and need not be repeated here. A standard adsorption apparatus and technique are used, consisting of the calibration of the dead space around the adsorbent with pure helium and then the measurement of the volume of nitrogen or other adsorbent required to fill the adsorption bulb containing the adsorbent at some given temperature and a series of pressures. At each pressure the helium calibration enables one to calculate the amount of adsorbate in the space around the adsorbent, and hence by difference to obtain the amount of adsorbate on the surface of the adsorbent. The experimental measurements are made at temperatures close to the normal boiling point of the adsorbate. The temperature of the bath thermostating the adsorbent during the run is carefully determined. The usual purification procedures are used on the various adsorbates employed.

Results

Up to the present time hundreds of experimental determinations of the surface areas of various porous and non-porous solids have been made by the low-tempera-

ture adsorption isotherm method with apparent success. For the purpose of illustrating the method, however, the results reported in the present chapter will be restricted to those materials for which some independent estimates of the surface area were available.

Carbon Blacks.⁶ A standard set of six carbon blacks was measured using nitrogen as adsorbate and a liquid nitrogen bath at about 78° K as a cold bath. The isotherms are shown in Figure 1 and the linear plots of the data according to equation 1, in Figure 2. The values for V_m and the surface areas are given below.

* Gehman and Morris.⁷

† Names here used were those on samples received by authors. However, theratomic carbon and Thermax are probably the same, "theratomic carbon" being used ordinarily to designate a class of carbons formed by thermal decomposition of hydrocarbon gases.

In column 5 of Table 2 are listed the diameters of the carbon black particles as calculated from the surface area measurements, on the assumption that the particles

are nonporous spheres and that their true density is 1.8. For comparison, in column 6 are shown the average particle diameters as determined by Gelman and Morris ⁷ on similar commercial samples in 1932. The agreement is probably satisfactory in view of the fact that the samples for the ultramicroscopic examination were prepared a number of years earlier than those for the nitrogen adsorption work.

Within the last year, measurements by means of an electron microscope on Micronex and acetylene black have been reported that are in almost exact agreement with the average diameter values obtained by the nitrogen adsorption method. For Micronex the electron microscope value is 0.028 micron; ⁸ that obtained by the nitrogen method varies from 0.028 to 0.031 micron depending on whether one uses 1.8 or 2.0 for the density of carbon. In the discussion attendant upon the ASTM Symposium on particle size measurements (March, 1941), it was disclosed that the electron microscope value for acetylene black is 0.050 micron; this compares with 0.052 micron that one obtains by the adsorption method using 1.8 for the density of carbon, and with 0.047, using 2.0 for the carbon density. This agreement is, in fact, much closer than we could consistently expect, since we have no way of knowing whether the correct value for the area covered by a nitrogen molecule adsorbed on the surface is more nearly 16.2 (Area L) or 13.8 square Ångströms (Area S). Even an approximate agreement between the results of the two methods, however, is exceedingly gratifying.

Zinc Oxide.⁶ Four samples of zinc oxide pigments on which measurements had been made by a number of different procedures were very kindly put at our disposal by the New Jersey Zinc Company. The nitrogen adsorption isotherms for the four samples are shown in Figure 3. The surface area values and calculated particle sizes are listed in Table 3.

Table 3. Surface Area Measurements on Zinc Oxide Pigments

| Sample No. | Weight of Sample (grams) | V_m (cc) | Area (sq m/g) | Average Particle Diameter (microns) |
|------------|--------------------------|------------|---------------|-------------------------------------|
| F-1601 | 5.492 | 11.89 | 9.48 | 0.115 |
| K-1602 | 6.444 | 12.95 | 8.80 | 0.124 |
| G-1603 | 7.403 | 6.56 | 3.88 | 0.28 |
| KH-1604 | 17.167 | 2.58 | 0.658 | 1.65 |

In Table 4 are summarized the results obtained on this standard set of zinc oxide

Table 4. Particle Diameters (microns) for Zinc Oxide Pigments Measured by Various Methods

| d_s by Nitrogen Adsorption | | | | |
| Using Area (L) values | 0.115 | 0.124 | 0.28 | 1.68 |
| Using Area (S) values | 0.135 | 0.145 | 0.33 | 1.97 |

samples by about six different methods. The values for the microscopic method have recently been compared by Ewing¹⁵ with his own results on the adsorption of methyl stearate. The ultramicroscopic values were furnished directly by the New Jersey Zinc Company and represent results obtained in their own laboratories. The measurements by the permeability method were made by Carman¹⁶ of South Africa and were forwarded to the author by the New Jersey Zinc Company.

An examination of the results in Table 4 reveals an excellent agreement among the values for samples F-1601, K-1602, and G-1603 as determined by permeability, ultramicroscopic examination, and nitrogen adsorption methods. The slightly larger values for average diameters on these three oxides obtained by the direct microscopic examination probably indicate the presence of some particles that are invisible under the microscope. The results obtained by the adsorption of methyl stearate agree more closely with the microscopic than with the other methods of determination, as might be expected if any capillaries between particles in small agglomerates are present, which are not readily accessible to the big organic molecules diffusing through a liquid medium. The results obtained on sample KH-1604 are really not comparable with each other, since the various samples of KH-1604 had not been treated identically. This is a reheated oxide that is known to contain agglomerates of particles that had been sintered together in the reheating process. The rubbing down of such samples in preparing slides for microscopic examination, or the use of the dispersion technique in preparing the ultramicroscopic samples would on such a sample of oxide certainly be expected to reduce the average particle size compared to that of the undisturbed agglomerated samples such as were used in the gas adsorption method.

Sized Microscopic Glass Spheres.¹⁰ The publication by Bloomquist and Clark¹⁷

of a method for preparing sized microscopic glass beads suggested a possible means of checking with considerable accuracy the nitrogen adsorption method for measuring surface areas. In Table 5 are listed the results of determinations on a sample of glass spheres furnished by Bloomquist. The sample was found to average about 7 microns in diameter as judged by microscopic examination. Furthermore, 90 per cent of the beads were supposed to be within two microns of the average. In agreement with this, the settling time in water according to our measurements was 84 minutes per 10 cm. Since the upper level of a mass of homogeneously dispersed settling particles would settle at a rate determined by the smallest particles present, the 5-micron value calculated from the settling time¹⁸ observed is consistent with the claims made for the homogeneity of the bead samples.

The diameters of the beads calculated from the adsorption measurements are 4.5 microns using area L values for the area per nitrogen molecule, and 5.3 using area S values as shown in Table 5. It appeared from these results that the original treat-

Table 5. Surface Area Measurements on Sized Glass Beads

| | |
|--|---------------|
| Area by nitrogen adsorption (area L values) | 5.52 sq. m/g. |
| Average diameter calculated from adsorption of nitrogen (area L) | 4.50 microns |
| Average diameter calculated from adsorption of nitrogen (area S) | 5.30 " |
| Diameter by microscopic observation | 7.20 " |
| Surface area after cleaning the beads with cleaning solution | 7.48 sq m/g |

ment of the glass spheres with cleaning solution might have roughened the surfaces enough to cause the surface area measured by the nitrogen isotherms to exceed somewhat the surface expected from the average diameter of the particles. Accordingly, the beads were subjected to an additional two-hour treatment by cleaning solution and remeasured. The surface area had increased 40 per cent as a result of this treatment. If one assumes that the original cleaning of the glass spheres had etched them enough to increase the surface area 40 per cent, the measured values of the particle size by nitrogen isotherms are in almost exact agreement with those obtained by direct microscopic observation. It appears, therefore, that for glass spheres the particle size determinations by settling through liquids, by microscopic examination, and by nitrogen adsorption are all in substantial agreement.

Discussion and Summary

Space does not permit the detailed discussion^{1, 19} of all the gas adsorption work on surfaces that has been reported in recent years. It may be stated by way of summarizing the present status of the method, however, that to the author's knowledge, no published data for surfaces for which independent area measurements are available can be correctly interpreted as contradicting the general conclusions of the present paper relative to the selection of V_m , the volume of gas corresponding to an adsorbed monolayer. On the other hand, a number of published results on surfaces for which independent area values were available seem definitely to confirm the ideas here expressed. As examples may be cited the results of Palmer and Clark¹¹ for the adsorption of acetone on a sample of powdered quartz glass whose surface area has been measured by the rate of solution in HF, and the results of Barrett, Birnie and Cohen¹² for the adsorption of water vapor on quartz glass particles whose area was obtained by a newly described method involving the projection areas of the individual particles.

The method here described for measuring surface areas is of course equally useful in some instances for calculating the particle size of finely divided substances. In conclusion, therefore, it may be well to set forth clearly the applications and

limitations of the low-temperature adsorption isotherm method for measuring surface areas and for estimating the size of microscopic or submicroscopic particles.

(1) Particle-size measurements of finely divided materials by the low-temperature gas adsorption method must be limited to non-porous solids; surface area measurements on the other hand, can be made for either porous or non-porous solids, since the "surface area" includes the inner as well as the outer or geometric surface of the particles.

(2) The particle-size calculations yield values for $d_s = \frac{6}{\rho S}$, where S is the total area in square meters per gram, ρ is the true density, and d_s is the average diameter of the particles in microns. Some assumption as to shape factors¹³ is, of course, involved. Calculations in the present paper assume the particles to be spheres or cubes.

(3) With nitrogen as a measuring gas in the temperature range 77° to 90° K and at pressures up to 760 mm, the method is applicable to samples having aggregate surface areas of at least 2 square meters. Samples of larger particles can be measured provided one uses high-vacuum technique²⁰ and works with some gas the saturation pressure for which is only a few millimeters of Hg.

(4) The gas used for making the low-temperature adsorption measurements must be inert toward the solid being measured; if it is chemisorbed by, or reacts chemically with the solid, the resulting surface-area measurements will be considerably in error.

(5) Layers of chemisorbed oxygen, hydrogen or other gases on the surface of the solid particles will not, according to past experience, affect the validity of surface-area measurements by the low-temperature physical adsorption method. However, it is necessary to remove by evacuation at suitable temperatures condensed films of moisture or other liquids that might exclude the measuring gas from some of the otherwise accessible surface between the individual particles.

(6) The S-shaped isotherms such as are shown in Figures 1 and 3 are characteristic of all results obtained with nitrogen on non-porous, finely divided solids up to the present time. It appears very probable, therefore, that low-temperature adsorption measurements plotted with the help of Equation (1) will furnish a reliable method for estimating the size of particles that are smaller than about 20 microns. There appears to be no lower limit to the size that can be studied, though the smallest particles to which the method is known to have been applied are about 0.003 micron in diameter, as reported recently by Smith, Thornhill and Bray.²¹

(7) Most of the work so far done has used nitrogen or argon for a measuring gas. Caution must be used in predicting the behaviour of miscellaneous vapors that might be used in place of nitrogen. As pointed out by Brunauer, Deming, Deming and Teller,²² some five different types of isotherms have so far been reported in the literature. It can be stated, however, that with nitrogen as a measuring gas only two substances have been found on which other than S-shaped isotherms of the kind shown in Figure 1 have been obtained up to relative pressures of about 0.5; these are, respectively, charcoal³ and chabazite,¹⁴ both of which yield flat, Langmuir-type isotherms, concave throughout to the pressure axis and supposedly characteristic of porous materials in which the capillaries are only a few molecular diameters in size.

(8) A detailed analysis of the present low-temperature adsorption method for measuring surface areas leaves little doubt as to its wide and general applicability, some gas such as nitrogen being used as an inert adsorbate. Nevertheless, there are some indications that big vapor molecules may yield surface-area values that differ somewhat from those given by nitrogen.²³ Accordingly, it is urged that the method should still be considered as one that is in the process of development and that may require some additional theoretical elaborations to account for results on all types of adsorbed molecules.

Adsorption and Crystal Habit Modification

WESLEY G. FRANCE

Ohio State University, Columbus, Ohio

The extensive and varied literature covering the subject of crystals is an excellent indication of the importance of the crystalline state of matter. Beginning with the observations of Steno,⁴⁷ in 1669, on the constancy of crystal angles, and continuing with the work of Haüy²³ leading to the "law of rational indices," on down to the present time, the volume of this literature has been growing at an increasingly rapid rate. This widespread interest is readily understandable when one considers the diverse fields in which a knowledge of the growth and properties of crystals is essential. Among these properties both size and shape have always been highly significant.

In some instances large, well-formed crystals are desired, as in crystal phonopick ups, crystal detectors, Nicol prisms, and infrared spectrographic prisms. Then again there is the opposite extreme, where exceedingly fine crystals are required, as in the production of the hydrous oxide gels and stable gold sols. Between these extremes many other examples are to be found. These include the production of paint pigments of increased hiding and covering powers; electrodeposition of metals made up of minute, strongly adherent crystals frequently giving rise to much-desired "bright plates"; the production of alloys and the control of their crystalline characteristics by heat treatment; the changes in crystal structure occurring during the setting of cements; and the need for fine crystals in various ceramic insulating and refractory bodies.

The organic chemist is frequently confronted with difficulties encountered in crystallizing certain organic compounds, and so also is the inorganic chemist in the preparation of pure compounds by recrystallization. The analytical chemist is often concerned with precipitations in which the crystals are too fine to be filtered or in which impurities have been adsorbed.^{25b}

The formations of gall and kidney stones have been shown to be crystalline in

structure.^{41, 51} The most common and direct complications which have occurred in the widespread use of some sulfonamide derivatives in therapeutics are anuria and/or hematuria, which result from the deposition of concretions of crystals of the drugs or their acetylated derivatives formed in the body.³⁰ The biochemist is interested in the crystallization of proteins⁹ and of synthesized vitamins. Recently, virus proteins have been crystallized and described.⁴⁶

Crystalline structure has been shown to have an important bearing on the properties of explosives. Cullen¹¹ states that detonating mixtures must have crystals of definite size and shape; also that lead azide can be rendered safe for handling by precipitation in the presence of adsorbable material so as to produce very small crystals.

With such a diversity of applications it is natural that investigations of the crystalline state should have proceeded along many lines. In this connection it is interesting to note that it was very early recognized that the various polyhedral crystalline forms were the result of some definitely ordered internal structure.^{43, 14} Nevertheless, it was not until the development of x-ray methods of crystal analysis that exact information concerning the internal structure and its effect on the external symmetry of crystals became known. As a consequence of this development, an extensive x-ray study of the structure of crystals has been in progress during the past two decades; this has come to occupy a most prominent place in crystallographic literature. This knowledge of the internal arrangement of the ions, atoms or molecules has been of great value in accounting for both the external form and many of the physical and chemical properties of crystals. Thus, for example, the ionic or covalent character of inorganic compounds can readily be established from x-ray examinations.

While such information is of great value, it is nevertheless insufficient, especially if one is chiefly interested in the properties of the surface of a solid rather than with those of the crystal as a whole, as in the adsorption of impurities by growing crystals. Although surface properties can be fairly well predicted from the internal structure,²⁷ it is becoming increasingly apparent that the mechanism of crystal growth must also be known in order that a complete understanding of the crystalline state may be gained.

Among the earliest observations of the modification of crystal habit is that of Robert Boyle,⁶ who noted that the normal shape of many crystals was changed by the "addition of other bodies." Somewhat later J. B. L. Romé de l'Isle³⁹ showed that NaCl grown in the presence of fresh urine formed octahedral crystals. In this connection it should be noted that Fourcroy and Vauquelin¹⁶ and Beudant⁴ produced octahedral crystals of NaCl from solutions containing urea.

Haüy²³ in 1801 observed that crystals of the mineral axinite colored violet by manganese have additional faces not present on those colored green by "chlorite." Senarmont⁴⁴ employed colored impurities to show that habit modification resulted from the adsorption of the impurity. Livizzari²⁸ noted that more carbon dioxide was evolved by the action of sulfuric acid on prism faces of calcite than on basic faces. Du Boisbaudran⁵ was among the first to recognize differences in the solubilities of the faces of a given crystal.

Ord⁸⁶ seems to be the earliest worker to use the term "colloid" in connection with crystallization, although not in its modern sense. He studied the effect of gelatin, albumin and similar substances on calcium carbonate, calcium oxalate, uric acid and other salts, and concluded their effect was physical and not chemical. Becke² accounted for the habit of a crystal by assuming that the crystal surrounds itself with faces of least solubility. Gibbs²⁰ considered the equilibrium between a crystal and its saturated solution, and developed the mathematical relations, including the interfacial tensions of different faces. He showed that, for complete equilibrium, the summation, over all possible forms which may appear on the crystal, of the prod-

uct of the total area of all faces of a given form by the interfacial tension for that form in contact with the saturated solution should be a minimum. Therefore, the decrease in the total surface energy must result in a given crystal habit. A limitation of this principle was imposed by Gibbs in his statement that the tendency of similiar crystals to assume the habit required by this principle would be inversely proportional to the linear dimensions of the crystals.

A closely related and better known theory was proposed by Curie.¹² According to this theory, each crystal face has a "capillary constant" defined as "that amount of energy which must be used to enlarge the surface one unit of area against the surrounding medium." The stable form would therefore be one in which the sum of the products of the areas of the different faces and their "capillary constants" would have a minimum value. Faces having small "capillary constants" would have small external fields of force and should grow slowly. They would also have the greatest area and be most prominent. It was later pointed out by Marc and Ritzel²⁹ that this theory would be valid only for crystals having faces of like solubility. However, they derived an equation which provides for such differences in solubility.

Noyes and Whitney³³ developed a theory in which the rate of solution appears as a function of concentration difference and the diffusion constant. Nernst³¹ further emphasized the importance of diffusion rates in his theory of reaction velocity in heterogeneous systems.

Gaubert¹⁹ crystallized phthalic acid from a number of dye solutions and determined the amount of dye adsorbed by the crystals. Changes in crystal habit were thought to be due to the formation of a solid solution.

The investigations of Marc and co-workers²⁹ on crystallization velocity and solution rate established the fact that dyes retarded the crystallization velocity but did not affect the rate of solution. From this it was concluded that crystallization was not the reverse of solution. Changes in habit modification were attributed to selective adsorption at the different faces.

With the advent of specific information covering the lattice structure of crystals as determined from x-ray studies, a better understanding of adsorption forces became possible. In this connection Langmuir²⁷ evolved his "surface active" theory, in which the chemical activity of a solid surface is thought to be dependent upon the spacing and arrangement of the atoms or ions comprising the surface layer.

On the basis of the lattice structure of the sodium chloride type, Niggli³² developed an interesting theory of crystal growth. According to his ideas, the residual valences of the sodium chloride lattice have components in the six directions of the cube, and planes passing through this lattice vary in the density of their ionic population. He considered the ionic layer, immediately below the crystal face, as possessing unsaturated or residual valences, and attributed the velocity of perpendicular face displacement to the thickness of that layer, this being zero for prominent and maximum for vicinal faces. With reference to crystals grown in the presence of adsorbable impurities, in accordance with this theory it appears likely that the adsorption is due only to those ions actually in the crystal face; the perpendicular face displacement results from the unused valences in the layer below the crystal face. Generally the growth forces are greater than the adsorptive forces, and vicinal faces disappear as the crystal develops.

Valeton⁵⁰ at about the same time suggested a theory of crystal growth similar to that of Niggli. Because of the electrostatic charges of the ions or atoms in the outer layer of a growing crystal, atoms or ions of unlike charge in the solution are attracted to the face and those of like charge are repelled. The cube faces of sodium chloride are made up of a checkerboard arrangement of positive and negative ions which tend partially to neutralize each other's fields. As a consequence, growth normal to these faces is slow. The octahedral planes are populated by ions of like

charge, and therefore normals to these planes should be directions of rapid growth. Furthermore, the net planes in forms of higher indices are spaced in such a way that the electrostatic forces are exerted through a number of layers, and the growth normal to such planes is also rapid.

An extension of this theory was presented later by Valeton.⁵⁰ He assigned a definite growth velocity to each face which was solely dependent on its ionic structure and independent of its size and environment. The rate of growth of any crystal face should therefore be the result of an equilibrium between its specific growth velocity and the rate at which ions can diffuse up to it.

Spangenberg⁴⁵ found, contrary to Valeton's theory, that the growth ratios of corresponding faces of potassium alum and sodium chloride were in many cases different. He thought that this was because of different lattice arrangements at the surface of the growing crystal.

Bentivoglio³ measured the rate of growth perpendicular to a crystal face and found that similar faces of a simple form grew at the same rate independently of their size. With complex forms having a variety of faces, unlike faces grow with different rates and like faces at the same rate, provided they are not close to a large face of a faster-growing form, in which case the latter produces a deficiency of the ion in the layers of solution in contact with the crystal.

A considerable amount of work on the adsorption of foreign matter by crystalline precipitates has been carried out. Paneth³⁷ concluded that the adsorption of ions by a lattice consists in the replacement of a similar ion for another at the surface of the crystal, the principal requirement for this exchange being that the compound formed by the adsorbed ion and the lattice ion be insoluble. Dyes were used to estimate the surface of the precipitate on the assumption that the adsorptions were monomolecular.

Fajans regarded the residual valences of the ions in the surface of the lattice as responsible for the adsorption of foreign ions by the crystal lattice. He extended Paneth's adsorption controlling factors by the inclusion of hydration, deformability, and agreement of size of the adsorbed and lattice ions.

Kolthoff^{25a} considers the adsorptive properties of ionic precipitates to be due to the residual valence forces of the ions at their surfaces. Furthermore the effectiveness of the ions is determined by their positions, those at the edges of the crystal being more effective than those within the plane and those at corners being more effective than either. He believes that crystal surfaces, instead of being plane, have submicroscopic pits and humps which become smoother on ageing.

The writer's interest in the adsorption of foreign substances by growing crystals developed from a series of studies of stability of suspensoid sols. With the establishment of the crystalline structure of the dispersed phase of a number of sols,^{42, 22, 52} it seemed highly probable that the growth forces of these colloidal crystals have an important part in the adsorption of the ions responsible for the stability of the sol. Furthermore, since the lattice structure was found to be the same for both macroscopic and colloidal crystals, it was thought that worthwhile information relative to suspensoid sol stability could be obtained by investigating the factors influencing the adsorption of foreign substances by macroscopic crystals during their growth from saturated solutions.

The work in this laboratory¹⁷ has been mainly concerned with the adsorption of foreign substances at the crystal-solution interface during growth and with the habit changes resulting from such adsorption. In this connection attempts have been made to learn both how the adsorbed ions, atoms or molecules are held in the crystal and the nature of the directive forces responsible for the adsorption.

These investigations have included: (a) the measurement of the changes in growth ratios due to adsorption; (b) the correlation of lattice structure with habit modification; (c) x-ray and electron-diffraction studies of crystals containing dyes

that have modified the crystal habit; (d) the determination of the quantity of dye adsorbed by growing crystals; and (e) the effect of the molecular structure of dyes on their adsorption by growing crystals.

At the outset it was clearly recognized that in order to establish a relation between crystal structure and the adsorption of foreign substances, a number of experimental conditions have to be met. These include: (1) the use of crystalline substances whose lattice structures are known; (2) the use of foreign substances of known molecular structure; (3) the selection of some crystallographic constant capable of accurate measurement whose value varies with the adsorption process; (4) in so far as possible the use of a single macroscopic crystal freely suspended in its saturated solution uninfluenced by the presence of other crystals.

These conditions were satisfied by the measurement of the growth ratio of a single crystal grown in the presence of dyes of known structure at constant temperature.

Studies of potassium and ammonium alums^{17d, e} led to the conclusion that the adsorption of any given dye by a growing crystal is a specific process dependent upon both the structure of the crystal and the shape, size, presence and orientation of polar groups in the dye molecule. In general the adsorption was greater on those faces having the stronger fields of force. Thus, in the case of the alums, the adsorption appeared to be entirely on the cube planes populated by ions of like charge, leaving the octahedral planes, populated by mixtures of positive and negative ions, clear and colorless (Figure 1).

FIGURE 1. Alum crystals before and after growth in presence of an adsorbable dye.

As a result of this preferential adsorption, the growth ratio 100/111 of potassium alum was reduced from 1.61 to 0.00 depending upon the concentration of dye present in the solution (Figure 2).

These results indicate the possibility of predicting the habit modification of any given crystal from a knowledge of its lattice structure provided its growth occurs in the presence of an adsorbable foreign substance.

That such predictions are possible was verified by the observation of the habit modification of sodium, barium, lead, and lithium nitrates, sodium bromate, potassium chloride and bromide, potassium and sodium sulfates, cupric acetate, urea, and finally citric and tartaric acids, grown in the presence of adsorbable dyes.

Since the growth of a crystal takes place as the result of the adsorption of its ions into the lattice, it is evident that the various polyhedral forms of crystals result from differences in growth velocities in specific directions. From this point of view a consideration of the habit and lattice structure of the alums indicates a high

Ammonium Alum

FIGURE 2. Growth ratio—concentration curves for ammonium alum.

specific growth rate for the cube faces such that the actual growth rate is strongly influenced by the rate of diffusion of the ions to the crystal face.⁵⁰ Therefore any condition such as stirring, or growth from supersaturated, rapidly cooling, or rapidly evaporating solutions, which increases the rate of diffusion, should increase the actual growth rate of the cube face and hence the growth ratio 100/111 of an alum

FIGURE 3. Adsorption of P- β OH-6 by potassium sulfate.

crystal. Precisely such effects were observed experimentally. Thus the growth ratio of pure potassium alum^{17j} was increased from 1.61 to 1.75 with the elimination of the cube faces by rapid stirring of the solution during growth. It was also found that when dyes were present, smaller quantities were adsorbed at the same concentration from stirred than from unstirred solutions.

In all cases, whether the solutions were stirred or not, neither Langmuir's adsorption equation nor Freundlich's adsorption isotherm adequately described the relation between the concentration of foreign matter in the solution and the amount

adsorbed by the growing crystal. The a -concentration curves (Figure 3) do not pass through the origin of the coordinate system but begin at a finite distance from the origin; that is, there is a minimum concentration of dye below which no adsorption occurs. However, at concentrations above this minimum a typical adsorption isotherm is obtained. This can be represented by a modified form of the equation of the adsorption isotherm as follows

$$a = kc^{1/n} - k'c^{-1/n'}$$

The second term of this equation appears to be in the nature of a "counter adsorption process" and is primarily a function of the dye concentration; it is infinite at zero concentration and even at relatively low concentrations rapidly approaches zero. It can be accounted for as follows. Normally, even in the presence of an adsorbable dye, the crystal takes up its own ions in preference to the dye, just so long as the crystal ions are readily available. If, however, the supply of lattice ions adjacent to the crystal face becomes depleted, because of rapid growth and slow ionic diffusion, the crystal will then satisfy its growth forces by taking up available and adsorbable dye ions, when their concentration becomes sufficiently great. The intercept of the curve on the concentration axis represents the minimum concentration of dye necessary to establish this condition.

The value of predicting habit modifications resulting from adsorption processes would be greatly increased if one could, at the same time, predict just what foreign substances would be adsorbed by a given crystal. However, attempts to make such predictions have thus far not been especially successful. This has presumably been caused, in part at least, by a lack of knowledge as to just how the foreign molecule or ion is adsorbed and held by the crystal.

The foreign ion or molecule may be held interstitially within the crystal interstices, or it may actually replace an ion in the crystal lattice, especially if there is an identity or close similarity in the size and shape of an active group in the foreign ion with that of the ion it replaces.

That the habit modification results from the adsorption of ions or molecules and not colloidal particles is indicated by the fact that solutions containing the dyes failed to show any relation between the number of colloidal particles present and the magnitude of the adsorption.^{17f, 1}

Measurements of the quantity of dye adsorbed and the total area of the ionic planes involved indicated that the dye was not adsorbed in a continuous monomolecular layer over the ionic planes. Thus, in the case of diamine sky-blue, the total area of the cube planes of an ammonium alum crystal was estimated to be 4300 times greater than the area covered by the adsorbed dye molecules.^{17f}

The marked dichroism frequently observed in the dyed crystals indicates a definite orientation of the dye. However, the absence of dichroism does not in itself suggest a complete absence of orientation, since adsorbed complex and elongated molecules may all be attached to the crystal in the same way, but may be coiled up so that rotation of the crystal makes no detectable difference in their refracting powers. Furthermore, there is the possibility of the adsorption of elongated molecules whose long axes are all parallel, but which nevertheless appear to be randomly distributed in polarized light due to rotation about one or more of the single bonds in the individual molecules.

Bunn⁸ has suggested that pleochroism and birefringence are due to colorless impurities. Gaubert^{19h} and Tamman and Laass⁴⁹ report pleochroism due to adsorbed impurities. Gaubert^{19g} explained the pleochroism he observed in cubic crystals of lead nitrate containing adsorbed dye, on the assumption of the presence of microscopic striations of dye, resulting from the simultaneous crystallization of the dye and crystal at certain concentrations, followed for a time by the deposition of nearly pure host crystal.

In order to determine how the presence and distribution of strong polar groups in the dye molecule affect its adsorption by a growing crystal, investigations^{17m, n, o} were undertaken in which a series of isomeric acid and basic monoazo dyes was used. These dyes were prepared by Griffith²¹ and Eberhart¹⁵ under the direction of Professor Wallace R. Brode for spectroscopic work, and were of an unusually high degree of purity. They were made by coupling aniline and the ortho-, meta-, and para-sulfonated anilines, by diazotization, with a series of mono- and di-sulfonic acid derivatives of α - and β -naphthols and α - and β -naphthylamines. For convenience these dyes are represented by abbreviations derived from the intermediates used in their preparation, as follows: (A) aniline; (O) ortho-sulfonated aniline; (M) meta-sulfonated aniline; (P) para-sulfonated aniline; (α -OH) α -naphthol; (β -OH) β -naphthol; (α -NH₂) α -naphthylamine; (β -NH₂) β -naphthylamine. Thus the scale model (Figure 4) is the structural representation of the sodium salt of the dye P- β OH. There were in all 38 acidic and 48 basic dyes. About half of these contained the nucleus

and the remainder the nucleus

Potassium sulfate grown in the presence of these dyes as impurity provided a number of interesting results.^{17m} The adsorption generally occurred on the (110) and (111) planes, which according to the ideas previously expressed, should therefore be those having the stronger fields of force. In order to aid in the interpretation of the data, scale models ($1\text{\AA} = 1\text{ cm}$) of the dyes and potassium sulfate were constructed (Figures 4, 5). For the latter the dimensions of the unit cell determined by Ogg and Hopwood were used.^{34, 35} The potassium sulfate model clearly showed the (100) planes to consist of a mixture of K^+ and SO_4^{--} ions and the (111) and (110) to be alternately either K^+ or SO_4^{--} .

That the $-\text{SO}_3\text{Na}$ group of the dye molecule is active in determining whether the dye is adsorbed or not is evident from the fact that when this group is sterically hindered or absent from the benzene ring the dye is not adsorbed. Also when this group is in the 1-, 4-, 5- or 8-position of the naphthalene ring, structural hindrances are encountered. Thus the most strongly adsorbed dyes were those in which the $-\text{SO}_3\text{Na}$ groups were in the meta and para positions in the benzene rings and 6- and 7-positions of the naphthalene rings.

In view of these results it seems probable that the adsorbed dyes are attached to the potassium sulfate crystals by means of the oxygen triangle of the $-\text{SO}_3\text{Na}$ group. These dyes ionize in solution, furnishing a large anion having a charge equal to the number of substituent $-\text{SO}_3\text{Na}$ groups, together with a sodium ion for each of the latter. The dye anion thus has three oxygen atoms in an equilateral triangle attached to a sulfur atom as in the SO_4^{--} ion, the remainder of the dye molecule assuming the position occupied by the fourth oxygen atom. It is therefore possible for the $-\text{SO}_3$ group of the dye anion to be substituted for the SO_4^{--} ion of the potassium sulfate crystal when present in favorable concentration.

Buckley had previously suggested^{7b, 8} such a means of attachment of RO_4^{--} and similar ions to the sodium chlorate crystal. He found that most substances that ionize to give an RO_4^{--} type ion result in the development of (111) planes of sodium

FIGURE 4. Model of dye P- β OH.

FIGURE 5. Model of potassium sulfate. Side elevation (100) plane.

chlorate at the expense of (100). He regarded the size and distribution of forces in the O_3 portion of the impurity ion as the main factor in determining whether that ion would obstruct the growth of the crystal. He later included dyes in his investigations and concluded that the mode of attachment of the dyes and foreign inorganic ions is identical.

The results obtained with potassium sulfate^{17m} suggested that the dipole moments

of the dye molecules might also be of considerable influence in accounting for their adsorption. Thus it was found that the dyes produced from the β -naphthol sulfonic acids were more effective than those from α -naphthol sulfonic acids. However, if NH_2 -groups were substituted for the OH-groups, the reverse was true, and those dyes prepared from the α -naphthylamine sulfonic acids were then more effective than those from the β -naphthylamine sulfonic acids. These facts, in terms of the dyes having the nucleus

mean that the most effective position for the $-\text{OH}$ group is ortho to the $-\text{N}=\text{N}-$ group, and for the $-\text{NH}_2$ group it is the para or 4-position in the naphthalene ring. Williams⁵³ found the dipole moment of the $-\text{OH}$ group to be -1.5 Debye units and that of the $-\text{NH}_2$ group to be $+1.7$. The dipole moments of the dye molecules would therefore be more nearly the same if the $-\text{OH}$ group were ortho and the $-\text{NH}_2$ group para to the $-\text{N}=\text{N}-$ group, assuming of course that the other groups remain in the same positions.

These dyes were also used as impurity with sodium nitrate, bromate and chlorate.^{17m} In the case of the latter salt, no habit modification was produced; however, four of the dyes colored the crystal uniformly throughout. The results obtained with sodium nitrate and bromate were in agreement with those obtained with potassium sulfate, except that the influence of the dipole moment appeared to be less evident.

X-ray powder spectrographs were made of dyed and undyed crystals of potassium alum, sodium nitrate, lead nitrate, and urea-sodium chloride.^{17g, 1, 1} In all cases the lattice constants were the same for the dye modified and the pure crystals. This identity of the lattice constants was evidently due either to the actual failure of the adsorption of the dye to affect the plane spacings, or to the inability of the x-ray method to detect such small changes as may have occurred. The former alternative was considered as indicating interstitial adsorption rather than ionic replacement.

However, because of the inconclusiveness of these x-ray studies, it was thought that electron diffraction investigations might be better, since electrons are more readily scattered than x-rays and therefore should be more satisfactory in a study of the surface structure of dyed and undyed crystals. An electron-diffraction camera was constructed^{17p} and single crystal reflection pictures of dyed and undyed sodium bromate crystals were taken. The measurements of these plates showed that the lattice constant of the habit-modified crystal was slightly but definitely greater than that of the pure sodium bromate. If further results prove this to be a real lattice stretching, and not due to an inner potential effect, it may be attributed to the replacement of the BrO_3^{--} ion by the large dye anion.

The results obtained by the writer and co-workers in their studies of the adsorption of foreign substances by growing crystals have led to the following conclusions:

- (1) The theories of Niggli, Valetton and Spangenberg are generally acceptable.
- (2) The adsorption of foreign substances by a growing crystal is dependent upon
 - (a) the lattice structure of the host crystal; (b) the residual valency force fields; (c) the ionic structure of the crystal face; and (d) the presence, size, shape, position and orientation of polar groups within the foreign molecule.
- (3) There appears to be no simple rule deducible from these observations, whereby one can predict what foreign materials will be adsorbed by any given crystalline substance.

- (4) From a knowledge of the lattice structure of a crystal it is possible to predict,

with some success, the habit modifications resulting from the adsorption of foreign substances during the growth of the crystal.

(5) Dyes in which $-\text{SO}_3\text{Na}$ groups are active in determining the adsorption are unlikely to be adsorbed if such groups are sterically hindered.

It should be pointed out in connection with the last of the foregoing conclusions that the converse is not necessarily true. There are many cases in which a dye is not adsorbed, even though its $-\text{SO}_3\text{Na}$ groups are not sterically hindered. This is illustrated in the case of sodium bromate grown in the presence of the following dyes:

The first is readily adsorbed and modifies the habit of sodium bromate; the second is not adsorbed; and the third is but slightly adsorbed without habit modification.

A number of workers in this field have not concurred in these conclusions. That this is so is rather to be expected, especially in view of the almost complete lack of knowledge available concerning the mechanism of crystal growth.

Buckley⁷ concluded that the adsorptions are more general and less specific than the writer considers them to be. He also questioned the importance attached to the residual valency force fields,^{7k} believing that while these force fields may "draw in" the impurity, something else, presumably located in definite spots in the molecule to "fit a similar orientation in the surface," is required to hold the impurity. This criticism is met by the writer's use of Buckley's theory of the mode of attachment of the dye, in which the oxygen triangle of the sulfonate groups replace the SO_4^{--} ions of potassium sulfate. Even so, this mode of attachment is not general, as there are many cases in which there appear to be no common characteristics between crystal and adsorbed substance, especially in reference to structural similarity.^{171, 18}

His investigations led him to assume a growth process, as suggested by Kossel,²⁶ in which the crystal grows row by row, with the rows forming in a single direction only on a given crystal plane.

In order to account for the fact that frequently only a small amount of dye is included in a crystal, he thought a periodic resolution process occurred in which most of the impurity was removed.

He recognized three types of adsorption: (a) the simplest type consisting of those cases explained by the adsorption of a known ion or molecule on one set of planes; (b) a more complex type in which there is an acceleration of the rates of growth

of certain planes, leading to their disappearance; and (c) a type in which a number of planes associated about an axis or face normal are affected together. Most of the theories so far proposed apply only to the first and simplest type of habit modification.

Frondel¹⁸ also questions the importance of the residual valence force fields. He cites as evidence the fact that out of 59 cases of dye adsorption by sodium and lithium fluorides, only four showed adsorption on the (111) planes, and that if the residual force fields were effective the adsorption should have been on the (100) planes.

One can also point to similar results by Reinders³⁸ with silver chloride and by Gaubert^{19b} with silver bromide and chloride. This is not necessarily an argument against the residual valency force fields. Rather it means that the structure of the crystals and the dyes used were such that a structural fit was impossible on the (111) planes but possible on the (100), under which circumstances the adsorption occurred on the weaker rather than on the stronger planes. From the outset, the writer has maintained that the adsorption is determined not alone by the residual valency force fields, but also by some structural relation between the dye and the crystal lattice, so as to enable either a part or all of the dye to be fitted into the lattice. In the majority of cases studied in this laboratory the adsorption has been found to occur on planes populated by like ions; and in the much fewer cases where it has been on the checkerboard type of planes the adsorption has been decidedly weaker.

Another objection, offered by Frondel, to the writer's use of residual valency force fields is that he believes it requires the fundamental assumption that there are differences in the surface energy between different faces of a crystal that are meaningful with reference to crystal growth and adsorption. However J. Willard Gibbs²⁰ has shown that such an assumption is not valid as applied to macroscopic crystals. In support of his objection Frondel cites the work of Cottrell.¹⁰ Since Cottrell was dealing primarily with equilibrium systems and not dynamic growth processes, the objection appears to be unwarranted. Furthermore, Cottrell's argument that the assumption of different diffusion rates to various crystal faces cannot be used to explain crystal habit is not pertinent, since the writer has never made use of such an assumption. The influence of diffusion is probably related to the specific growth rate of a given crystal face in the manner suggested by Valeton.⁵⁰

Frondel's criticisms are based in part on the work by Kossel²⁶ and Stranski⁴⁸ on crystal growth. They analyzed a mechanism of growth of macroscopic crystals of the sodium chloride type from a consideration of the energy relations involved. Kossel has made calculations for the relative energies released by the deposition of an ion upon the (100) or the (110) planes of the sodium chloride type of crystal. It seems however that this treatment is rather limited in that it has proved satisfactory for only the external fields of electrically neutral crystal faces.

Certainly the Kossel-Stranski theory, in which the ions are deposited row by row on the cube faces of sodium chloride type crystals, provides a much more regular and uniform growth than can be offered by the deposition of ions on the (111) planes due to residual valency force fields. However, it has been pointed out by Davey¹³ that there is much evidence indicating that crystal growth takes place along a sort of three-dimensional lattice work, which is later filled in with crystal material, rather than proceeding uniformly along a plane surface. Furthermore, according to Kleber,²⁴ the theory of Kossel and Stranski is not applicable when adsorption and other secondary effects predominate.

Bunn⁸ has proposed a theory of adsorption and crystal growth employing the basic concepts developed by Gaubert^{19a} that the inclusion of impurity in an oriented form, the parallel growths of one crystal on a larger crystal of another substance, and the habit modification of a crystal are all closely related phenomena. One point stressed is that information at hand concerning mixed crystal formation can be

advantageously applied, with necessary modification, to adsorption problems, since mixed crystals and adsorption bodies apparently differ only in degree. In this connection it is emphasized that while a complete identity of lattice structure is required for stable mixed crystal formation, a similarity of the lattice structure of the two substances along certain planes only is necessary for strong oriented adsorption and unstable mixed crystal formation. Bunn makes use of the instability of the mixed crystal to account for habit modification; he states that, from his point of view, the conditions for adsorption and habit modification and oriented overgrowth are alike, and that modification of habit should be reciprocal. He also found evidence in support of the opinion that a redissolving process takes place concurrently with growth.

While there are undoubtedly pairs of substances that support Bunn's views and exhibit reciprocal habit modification, nevertheless such an explanation, by its requisite of identity of lattice structures, must fail to account for a very large proportion of adsorptions and habit modifications. In other words Bunn's theory is highly restricted and therefore greatly limited in its application. Thus, Frondel¹⁸ observed two types of adsorption, only one of which appeared to be in harmony with it.

Royer,⁴⁰ in a series of papers, expresses agreement with Bunn in reference to the necessity for similarity of lattice structure in the absorbed substance and growing crystal.

Balareff and co-workers¹ have developed an interesting theory of "inner adsorption" for crystal growth in which it is assumed that the growth of an actual crystal, as distinguished from an ideal crystal, occurs at a large number of unrelated nuclei distributed over the entire surface of the crystal, and that each nucleus ceases to grow when it comes in contact with neighboring nuclei. The resulting macro-crystal is therefore a mosaic of tiny crystals of colloidal dimensions. When growth has stopped, foreign substances can be adsorbed on the exposed crystal faces within the macro-crystal. While there is extensive evidence in favor of the general existence of imperfect crystals, it is difficult to see how Balareff's theory can be used to explain adequately the marked and preferential adsorption that takes place on certain crystal faces during growth in the presence of impurities.

A consideration of the various theories of crystal growth and adsorption presented here indicate that of Buckley, based on the Kossel-Stranski theory, and that of Bunn to be complementary. The writer has had somewhat the same viewpoint as Buckley, but differs in using the residual valency force fields in a way more nearly corresponding to Valetton's theory than to that of Kossel and Stranski.

Differences of opinion such as expressed by the various workers studying crystal growth and adsorption phenomena strikingly emphasize the need for exact knowledge concerning the way in which a crystal grows, in order that an understanding of adsorption and habit modification processes may be gained.

Admittedly, comparatively little is definitely known concerning adsorption by growing crystals, even though the volume of literature on this subject is rather extensive and varied. This situation is in itself a strong argument for further work in this interesting and important field.

Such work should certainly include additional studies of the Kossel-Stranski theory by extending the energy calculations to more complex crystal systems. The following investigations are either in progress or contemplated in the writer's laboratory: (a) a study of the adsorption of dyes with known dipole moments; (b) the use of the mono-azo series of dyes with ammonium sulfate which is isomorphous with potassium sulfate, and also with tartaric acid which crystallizes in the triclinic system; (c) an extension of the electron diffraction and x-ray studies of modified and unmodified crystals; and (d) use of the electron microscope in an attempt to learn more about the "fine structure" of the crystal surfaces.

Some preliminary studies have already been made with the electron microscope^{17p}

and tiny crystals of apparently perfect form having dimensions smaller than 5×10^{-5} cm have been observed, together with some irregular forms difficult to account for. This preliminary study indicates the great need of further work, using crystals of known fine structure in order to interpret correctly the images resolved. In this connection it would no doubt be very much worthwhile to parallel the electron microscope investigations, using the same materials, with the ultraviolet light microscope. Furthermore, much needs to be done in the direction of the preparation and mounting of the samples for observation with the electron microscope. These and many other investigations will doubtless be carried on as the full power of the electron microscope in crystallographic studies comes to be realized.

Some Applications of Selective Adsorption and Differential Diffusion in Chemical Analysis

BEVERLY L. CLARKE

Bell Telephone Laboratories, Inc., New York, N. Y.

Adsorption and Diffusion

If one begins with a homogeneous mixture of several chemical species, and establishes an interface, concentration gradients may spontaneously set themselves up with respect to one or more of the species, in the region of the interphase boundary: this is adsorption. Equilibrium is established when the interfacial energy has attained a minimum, which is predictable from the Principle of Least Energy; whence arises Gibbs' Law, that the intensity of the adsorption of a substance at an interface parallels its capacity to lower the interfacial energy.

The theory of adsorption presents the following qualitative picture: a molecule below the surface boundary of a solid, liquid or gas is completely surrounded by other molecules, so that the attractive forces emanating from it tend to be neutralized. But a molecule *at* the surface is not completely surrounded by its fellows, and therefore possesses unneutralized affinity, or energy. If now some substance dispersed in one of the contiguous phases has the capacity, if present at the interface, to neutralize some of this residual energy, it will spontaneously proceed to the interface. In other words, for the originally existing energy gradient across the interface there is substituted a concentration gradient.

The process by which material aggregates proceed to an adsorbent interface might be termed directed diffusion; as a molecule of the uniformly dispersed adsorbate-to-be just below the interface is adsorbed, another moves up to take its place, and this process continues until equilibrium, as expressed by the well-known adsorption isotherm, is reached. Thus diffusion, the natural function of which is to eliminate concentration gradients and produce uniform dispersal, is inveigled into becoming a party to the attainment of the precisely opposite result. Nevertheless, at equilibrium, the great principle that diffusion serves—the Second Law of Thermodynamics—still operates; and thus the state of equilibrium represents a dynamic balance between two opposing forces, that of adsorption and that of diffusion.

There is another important way in which the force of diffusion may be made to accomplish the attainment of heterogeneity, the most familiar exemplification of which is the process of dialysis. Here diffusion would pass both colloid and crystalloid through the membrane, as in all other directions, but the membrane retards the

passage of the colloid, so that the process becomes differential diffusion and results in a separation.

Similarly, adsorption is selective in that the forces by which different substances are drawn to and held by a given adsorbent are in general different. Thus the process of adsorption from a mixture of substances results in an adsorbate whose components are in a different ratio from that in the original mixture.

Capillary Effects

If we limit our consideration to adsorption at gas-liquid interfaces, we are not concerned with capillarity, for matter in these states, although discontinuous in the molecular sense, and possessing at any given instant in time a network of intermolecular voids, lacks entirely the rigidity and permanence of structure that characterize the solid state. (There are of course gradations, in respect to structure, between the ideal solid and the ideal liquid, as in the colloidal gel.) But the applications of adsorption and differential diffusion to chemical analysis that will be discussed in this chapter involve the use of solids having a porous or capillary structure, and capillarity plays a part in the processes.

Leonardo da Vinci first recorded observations of capillary phenomena, and as early as 1718 Jurin's Law was enunciated. This law can be expressed as follows:

$$rh = \text{constant},$$

where r is the radius of the capillary and h the height of rise. More recent work has evaluated this constant, leading to the formula:

$$rh = 2\gamma/dg,$$

where γ is the surface tension of the liquid against air, d the density of the liquid, and g the gravitational constant. It is clear that the effort of Nature to reduce interfacial energy underlies capillary phenomena, as it does adsorption.

Inherent Applicability of these Phenomena to Analysis

Selective adsorption, differential diffusion and capillarity are phenomena that are fundamental to many natural and technological processes. When rain soaks the soil and later on the sun and wind aid evaporation at the surface, the salts and other diffusates tend to become sorted out in the vertical profile of the soil according to their diffusibilities and adsorption affinities. Similarly, calcium sulfate in bricks may accumulate toward the surface on weathering, where it forms the familiar white excrescence; and sticks of "chalk" (really cast rods of plaster of paris) often show a hard skin which makes writing on the blackboard difficult until it is broken down. Alexander² pointed out that diffusion concentrations occur in the preparation of foods, such as in the crust of bread; and it is often a question whether or not beneficial accumulations of vitamins and salts may exist in other crusts and in the outer sheaths of edible fruits and vegetables. The role of these phenomena in biological processes is too well known to require elaboration here.

Our particular concern in this chapter is the application of these effects in chemical analysis. It has been pointed out that adsorption and diffusion, alone or in combination with capillarity, cause separations of mixtures into their components: this is analysis, in the sense that it is the opposite of synthesis. Moreover, such separations are an essential preliminary to many methods of qualitative and quantitative analysis, to all methods, in fact, that require the isolation of the substance under examination before it is identified or measured. If we have a solution to analyze for A and B, we may, by classical methods, fractionally precipitate as the hydroxides, obtaining for eventual weighing two precipitates, one containing all the A and the other all the B. By perfect analogy, we may alternatively shake the solution first with a selective adsorbent for A, then, after filtering, with one that adsorbs B.

Thomas Graham recognized the analytical importance of diffusion, as is shown

by the opening paragraph of his paper entitled, "Liquid Diffusion Applied to Analysis"³:

"The property of volatility, possessed in varying degrees by so many substances, affords invaluable means of separation, as seen in the ever-recurring processes of evaporation and distillation. So similar in character to volatility is the diffusive power possessed by all liquid substances, that we may reckon on a class of analogous resources to arise from it. The range also in the degree of diffusive mobility exhibited by different substances appears to be as wide as the scale of vapor tensions."

Goppelsroeder's "Capillary Analysis"

The use of filter paper as a medium for carrying out analytical reactions is a very old device indeed. Thus lead acetate paper for detecting hydrogen sulfide is described in textbooks published as early as 1850, and in 1861 Schönbein,⁴ the discoverer of ozone, proposed the use of starch-potassium iodide paper for detecting that substance. But these employments of paper made only incidental use of the adsorptive and capillary properties of the network of cellulose fibers that is paper.

It was left to Goppelsroeder^{5, 6} to devise a method of "capillary analysis" in which these properties were deliberately taken advantage of, and for which the claim⁷ was made that it could detect the presence of 10^{-11} gram of methylene blue in 1 cubic centimeter!

Strain^{8, p. 7} gives what is considered to be an adequate discussion, for the present purposes, of the Goppelsroeder technique:

"In the same year that Tswett first reported the use of adsorption columns [see section on Spot Tests], Goppelsroeder described a somewhat similar analytical method known as capillary analysis. According to this method, one end of strips of adsorptive paper are placed in solutions of the pigments or other materials to be resolved. As the liquid is drawn into the paper by capillary forces, the substances in solution gradually separate from one another forming a series of bands analogous to those observed in the Tswett columns. The rate of flow of the solvent into the paper strips can be increased by hanging them over the edge of the vessel containing the solution of the mixture. To some extent the bands may be separated from one another by placing the paper strips in a portion of the fresh solvent after some of the solution has been adsorbed.

"In principle the capillary analysis procedure is similar to the columnar technique. However the development of the chromatogram is rather difficult and the preparation of materials in quantity is virtually impossible. As a consequence, capillary analysis has not found extensive use. A recent modification of the Goppelsroeder technique in which the paper alone or paper dusted with adsorptive powders is placed between glass plates⁹ is subject to the same limitations as the original method. Various applications of the capillary analysis methods have been ably reviewed by Rheinboldt."¹⁰

To this it is only fair to add that, although Goppelsroeder did not publish his full-fledged capillary analysis method until 1906, this publication⁵ was essentially a summary of his previous work, extending back to 1861. It should also be noted that Goppelsroeder appears to have conceived his work in this field as an outgrowth of that of Schönbein; and that Freundlich^{11, pp. 289-90} considered that the method had considerably greater potentialities than have materialized.

Chromatographic Analysis*

Historical. In 1906 the Russian botanist, M. Tswett, working at Warsaw, published the description of a method of resolving mixtures by selective adsorption on

* The task of the writer attempting to summarize the work on chromatography is greatly facilitated by the availability of two recent monographs on the subject, that by Strain⁸ and that by Zechmeister and collaborators,¹² as well as an even more recent review by Strain.¹³ The reader is referred to these for details and complete bibliographies.

porous columns of suitable materials. This technique was the culmination of a number of years of experimentation on the isolation of plant pigments, and may be generally described as follows:

If a solution is caused to percolate unidirectionally through a closely packed column of powdered adsorbent material, with or without electrophoresis, one or more of the components of the solution may be to some degree retained by the adsorbent; and on subsequent percolation of the pure solvent through the column, the adsorbates may be further separated and concentrated in discrete bands of the column. The substances thus separated, after chemical fixation if desired, may be examined *in situ*, or removed from the adsorbent by means of eluants.

It had, of course, long been known that certain substances, such as charcoal, if shaken with solutions of dyes and the like, remove some of the dissolved materials from solution. Practical applications had been made of this, as in the decolorization of molasses. But in all these cases one effected the separation of the solutes as a whole from the solvent and not from one another. Tswett seems to have been the first to conceive the possibility of making use of the selectivity of adsorption to bring about such desired separations. In the view of the writer, Tswett's fundamental discovery was that this selectivity could be taken advantage of if the flow of the solution through the adsorbent were unidirectional.

Theory. It must be stated that up to the present the chromatographic method has remained on a basis that is largely empirical. If one wishes to separate a new mixture, there are almost no guiding principles of theory to assist in the selection of the adsorbent, the solvent or the eluant, and if the mixture has no discernible features of analogy with mixtures previously studied, one must resort to trial and error. There is no reason to doubt, however, that an adequate theory will emerge in time. On the other hand, as will be discussed later, there is gratifying correlation between the structure of certain series of organic compounds and the relative positions of their bands when adsorbed on the Tswett column.

If, however, a proper solvent and a proper adsorbent are assumed for the chromatographic separation of a given mixture, Wilson¹⁴ offers a mathematical theory that accounts at least qualitatively for the experimental results. Wilson treats first the simple case of the adsorption of one solute. He assumes a long column containing M grams of adsorbent per centimeter length, and sets himself the task of formulating the distribution of adsorbed material in the column after a volume, v , of a solution containing solute at an initial concentration c_0 has passed through it. Two simplifying assumptions are made: (1) that equilibrium between adsorbed material and the solution in contact with it is always maintained, and (2) that the volume of the interstices between the particles of adsorbent per unit length of column is negligible.

If Q is the number of millimoles of adsorbed solute per centimeter length of column at a point where the solute concentration is c , an adsorption isotherm is assumed of the form $Q = Mf(c)$. If now the distance from the top of the column to any lower point in it is x , the following differential equation can be derived:

$$\left[\frac{\partial}{\partial v} (Mf(c)) \right]_x + \left(\frac{\partial c}{\partial x} \right)_v = 0,$$

whose general solution is,

$$c = \Phi [v - Mxf'(c)],$$

where ϕ is an arbitrary function.

By inserting the appropriate boundary conditions, the following discontinuous solution is arrived at:

$$\text{For } 0 \leq x < \frac{vc_0}{Mf(c_0)}, Q = Mf(c_0);$$

$$\text{for } x > \frac{vc_0}{Mf(c_0)}, Q = 0.$$

Wilson's assertion that "the discontinuous nature of the solution accounts in a satisfactory way for the sharpness of the bands observed in chromatographic experiments," appears reasonable. He also points out that the solution, $Q = Mf(c_0) = \text{const.}$, "is in accordance with the experimental observation that the intensity of color is approximately uniform throughout the band." Wilson also considers mathematically the case of n solutes.

In a discussion of Wilson's paper, Meyers^{15, pp. 341-2} writes as follows: "When a sufficient volume of solution has been fed to the column to extend $vc_0/Mf(c_0)$, the length of the band, to l , the length of the column, 'breakthrough' occurs. Since breakthrough is expressed as grams adsorbate per gram adsorbent, and since

$$vc_0/lM = f(c') = \frac{\text{gms adsorbate}}{\text{gms adsorbent}} = \text{capacity},$$

a knowledge of adsorption isotherms should permit a calculation of breakthrough capacity of columns of adsorbents when breakthrough occurs."

Wilson's work is a very promising beginning on a comprehensive theory of chromatography, and it is to be hoped that its development will be carried forward.

Technique. The basic technique of chromatography is extremely simple and straightforward. It consists of the following steps:

- (1) Formation of the chromatogram, *i.e.*, percolation of the solution through the column of adsorbent.
- (2) Development of the chromatogram, *i.e.*, percolation of fresh solvent to widen and separate the bands.
- (3) Elution of the substances separated by extracting the several sections of the column corresponding to the bands, with polar solvents.

Since the writer does not intend to give laboratory directions for chromatography, it will suffice to state that a number of variables and secondary factors have been recognized and studied, in addition to the chemical nature of the adsorbent, the solvent, and the eluant. Among these are: firmness of binding of adsorbates to adsorbent; particle size and porosity of adsorbent; avoidance of exposure of column to air in certain cases; poisoning of adsorbent; effect of one adsorbed compound on another; size and shape of adsorption columns; preparation of adsorption columns; concentration of solutions; rate of percolation; and techniques of development and elution.

Among the variations in the basic technique that have been published is the drawing of the solution from the bottom of the column upward, and the location of the boundaries between bands in the liquid emerging from the top of column by the use of the Toepler schlieren effect.²⁵ Other workers have eluted the successive bands without removing the column from the tube, by washing with fresh portions of solvent until each compound was carried in succession into a separately collected percolate. The modifications are useful when working with colorless compounds whose adsorption boundaries are difficult to locate. Ultraviolet fluorescence, and the brushing on of a thin line of a reagent that forms colored products with the adsorbates, have also been used to locate the boundaries.

Adsorbents. The outstanding fact about chromatographic adsorbents is that no

relation has been discovered between their chemical structure or composition and their adsorption capacities. Not only is there no approach to a universal adsorbent, but none has been found that is perfect even for a restricted application.

The ideal chromatographic adsorbent for a given mixture would have these characteristics, possibly among others:

- (1) High adsorption capacity for all the solutes, yet not so high as to make development or elution difficult.
- (2) Sufficiently different specific adsorption capacities for the several solutes to permit their separation by development of the chromatogram.
- (3) Absence of capacity to cause chemical changes in adsorbate, solvent or eluant.
- (4) Non-porous particles of uniform and suitable size.
- (5) Whiteness or absence of color.

Since it is impossible to write a specification for an adsorbent as we would for a chemical reagent, in terms of desired chemical and other characteristics, the best we can do is to require that successive lots of a given adsorbent be prepared by the same process from the same raw material. Magnesia or alumina or soda ash prepared in different ways often show gross differences in performance in the Tswett column. This fact renders much of the older literature on chromatographic adsorbents difficult of interpretation. Tables 1 and 2 show the applications and relative adsorption capacities of some of the commonly used adsorbents.

Table 1. Adsorbents and Solvents Useful for Chromatographic Studies of Various Substances (Strain⁸, p. 49)

| Substance | Adsorbent | Solvent |
|--------------------------------|---------------------------|---|
| Inorganic ions | Alumina | Water |
| " " | 8-hydroxyquinoline | " |
| Enzymes | Bauxite | " |
| Sugars | " | " |
| " | Bone Ash | " |
| Flavins | Frankonit | " |
| Anthocyanins | Alumina | " |
| Alkaloids | " | " or benzene |
| Amino acids | Titania | Water |
| Chlorophylls | Saccharides | Pet. ether & benzene |
| " | Magnesium citrate | Pet. ether & ether |
| Chlorophyll derivatives | Talc or saccharides | Benzene, ether or alcohols |
| Nitro compounds | Talc | Benzene |
| Organic acids | " | " |
| Phenols | Lime | Alcohols |
| " | Alumina | Benzene |
| Ethers, ketones, esters | Alumina | Pet. ether & benzene |
| Xanthophylls | " | Benzene |
| " | Magnesia | 1, 2-dichloroethane |
| " | Alkaline earth carbonates | Pet. ether, benzene or carbon disulfide |
| Aliphatic alcohols and sterols | Alumina | Pet. ether & benzene |
| Unsat'd hydrocarbons | Lime, alumina or magnesia | Pet. ether, carbon tetrachloride or benzene |
| Sat'd hydrocarbons | Alumina or magnesia | Pet. ether |

It was stated that adsorbents should not interact chemically with the adsorbates. There are, however, modifications of the basic chromatographic technique in which chemical reaction seems to be necessary to effect the separation. Thus, separations of inorganic ions by adsorption on 8-hydroxyquinoline involve reversible chemical reactions with the adsorbent, fractionation of isotopes on permutit is accompanied by ion-exchange reactions, and the adsorption of certain dyes produces color changes indicative of complex formation.

Table 2. Adsorbents Arranged in Approximate Order of Adsorption Capacity (Strain⁸, p. 50)

 Activated magnesium silicates
 Activated alumina, charcoal and magnesia (Micron Brand)
 Fuller's earths

Solvents. The choice of a solvent for a mixture to be resolved chromatographically is guided by the following considerations:

- (1) The mixture should have sufficient solubility in the solvent.
- (2) The adsorbent to be used must be capable of extracting the solutes from their solution rapidly and completely. Since the process of forming a chromatogram is a competition between the adsorption capacity of the adsorbent and the solvent power of the solvent, highly polar solvents are in general to be avoided.
- (3) There must be available an eluant of higher solvent power.
- (4) The solvent should not react chemically with the adsorbent, the solutes or the eluant and should be stable.

Table 3, taken from Strain,⁸, p. 66 lists the important solvents according to the readiness with which they give up their solutes to adsorbents.

Table 3. Solvents Arranged in Approximate Ascending Order of Stability of Their Solutions to Adsorbents

Petroleum ether, b.p., 30-50°
 " " " 50-70°
 " " " 70-100°
 Carbon tetrachloride
 Cyclohexane
 Carbon disulfide
 Ether (anhydrous, alcohol-free)
 Acetone (anhydrous, alcohol-free)
 Benzene
 Toluene
 Esters of organic acids
 1, 2-Dichloroethane, chloroform, dichloromethane
 Alcohols
 Water (variations with changes in pH and salt conc.)
 Pyridine
 Organic acids
 Mixtures of acids or bases with water, alcohol or pyridine

Eluants. From what has been said about solvents, it will be clear that an eluant must be so chosen that in the competition between it and the adsorbent, in the elution process, the eluant must prevail, rapidly and completely. Thus, liquids arranged, as are those in Table 3, in descending order of usefulness as chromatographic solvents, are automatically arranged in *ascending* order of efficiency as eluants. Polar solvents are generally the best eluants.

It will be obvious from the discussion of adsorbents, solvents and eluants, that the choice of any one is dependent on the other two, and that the roles of solvent and eluant may interchange from one experiment to another.

Electrophoresis. In the usual application of electrophoresis, charged particles in a liquid are caused to migrate toward one or the other of a pair of electrodes, by the application of an EMF. Since particles chemically different move in general at different rates, this technique can be used to effect separations. A disadvantage is that convection currents exist in liquids and these tend to reduce the sharpness of the boundaries and the cleanness of separation. A combination of electrophoresis with chromatography has been used which in some cases produces better results than does either technique alone. A mixture of solutes that is adsorbable as a whole but whose components are difficult or tedious to separate by unaided chromatography can sometimes be more rapidly resolved, after adsorption on a Tswett column, by the insertion of electrodes at the top and bottom of the column and the application of an EMF. Convection currents are minimized and the boundaries remain sharp.

What chromatography can do. This technique has for its primary objective the resolution of mixtures. Such resolutions have been carried out for the following purposes:

- (1) Qualitative analysis.
- (2) Quantitative analysis.
- (3) Determination of molecular structure.
- (4) Testing substances for chemical homogeneity.
- (5) Establishing identity or non-identity of substances.
- (6) Purification of substances.
- (7) Concentration of materials from dilute solutions.
- (8) Control of technical products.
- (9) Regeneration of substances from complex addition compounds.

There will be found in Zechmeister's¹² and Strain's⁸ books full details and many examples of these nine types of problems for which chromatography has been found useful. Perhaps the most interesting application, from the viewpoint of theoretical chemistry, is the determination of molecular structure of organic compounds, some examples of which may properly be reviewed here.

Generally speaking, adsorbability of organic compounds increases with the number of polar groups in the molecule. A classical example is the series of synthetic polyenes,¹⁶

To summarize the experimental results, the larger n , the stronger the adsorption, and hence the higher in the column is the adsorption band.

The same order of adsorption is obtained if the phenyl groups in these polyenes are replaced by certain heterocyclic groups, to form, for example, the indolenine series of dyes:¹⁷

Extensive chromatographic investigations have been made of the carotenoid pigments, and much valuable information on structure has been obtained. These substances are yellow to violet fat-soluble pigments. The results illustrate the fact that, with complex organic molecules, not only the double bonds but other polar groups, such as hydroxyl and carboxyl, affect the order of adsorption, so that interpretation of the chromatograms in terms of structure may be very difficult. In this series of

compounds it was found that the adsorption affinity increases, with compounds otherwise analogous, when¹⁸

- The number of conjugated double bonds increases.
- Of a given number of double bonds, all are conjugated.
- OH groups occur in unsaturated systems otherwise identical.
- OH groups occur in unsaturated systems otherwise identical.
- The number of OH groups increases.
- A carboxyl group is conjugated with a carbon double bond.

Table 6. Adsorption Series of Some Polycyclic Compounds.

*Naphthalene**Pyrene**1, 2-Benzpyrene**Phenanthrene**Chrysene*

As Strain⁸, p. 15 puts it: "In homologous series of organic compounds, the adsorbability increases with an increase in the number of double bonds. . . . Among compounds of the same type, adsorbability also increases with an increase in unsaturation. . . . Among isomeric compounds such as the polycyclic hydrocarbons . . . there is no simple relation between the number of double bonds and adsorbability. The shape and polarity of the molecule, as indicated by color, appear to exert greater influences than the number of double bonds alone." These relationships are illustrated in Tables 4, 5 and 6.

Recent Literature. There will be found in the books by Zechmeister¹² and Strain,⁸ and in the review paper by Strain,¹³ a complete bibliography of the chromatographic technique through 1941. The following additional papers have become available during 1942:

Schuler and Yang,²⁶ using as adsorbents alumina, calcium carbonate, and mag-

nesia, separated certain isomeric nitro-compounds, nitration products, and homologous quinones.

Tiselius^{27, 28} continued his work using the Toepler schlieren effect to locate boundaries, and applied the method to glucose and lactose solutions. He reports that the adsorption of saccharides from aqueous solutions by carbon is governed chiefly by the size of the molecule.

"Chromatographic Analysis in Reverse" was described by Lowman.²⁹ In this, a tube is mounted vertically and its bottom closed with a cork. Pure solvent is poured in, on top of which is poured the solution. A funnel dips several centimeters into the solution. The powdered adsorbent is added in successive small amounts. The compounds in the mixture are carried to the bottom in the order of their adsorbability. When the adsorption is complete more powder is added, and the column is pushed out of the tube, as in usual chromatographic analysis.

Bretschneider³⁰ separated androstenedione and progesterone from sterol oxidation products by adsorption on alumina from benzene-petrol ether solution. He also separated cholestanone and cholestenone by adsorption from petrol ether on silica.

Working in the inorganic field, Venturello and Agliardi,³¹ using alumina as adsorbent, determined the following order of adsorption from aqueous solutions:

Ca, Pd, Pt (strongest adsorption)

Au

(Mo)

As

(Bi, Ga, Os, Th, ZrO)

Co, Cr, Cu, Fe, Hg, Ni, Pb, UO₂, V

Ag

Be, Cd, Mg, Mn, Tl, Zn (weakest adsorption)

Bielenberg and Goldhahn³² determined pyrocatechol, resorcinol and phlorglucinol in the presence of each other in aqueous solution by treating with ferric chloride followed by deposition on alumina. Better results were obtained when they used the azo dyes of these phenolics in benzene-isoamyl alcohol solution.

Erlenmeyer and Schmidlin,³³ using the following adsorbent system:

cotton pad

starch plus 5-oxo-4-oximino-3-phenylisoxazoline

cotton pad

starch plus violuric acid

cotton pad,

obtained good separations, from the aqueous solutions of their acetates, of potassium (yellow zone) and sodium (red zone).

Erlenmeyer and Schönauer,³⁴ using violuric acid alone or with starch, barium sulfate or diatomaceous earth, as adsorbent, separated potassium, calcium, magnesium and sodium as acetates in water solution. Good separations were obtained with potassium-sodium, ammonium-sodium, potassium-magnesium, magnesium-sodium, ammonium-magnesium, barium-calcium, strontium-calcium, cupric-mercuric, plumbic-mercuric and cupric-plumbic. The results with potassium-ammonium and barium-strontium were poor.

Crowe³⁵ described a "Micromethod of Chromatographic Analysis." A Petrie dish was fixed in a tilted position, and a layer of adsorbent powder shaken down to cover part of the lower half of the bottom, in the form of a wedge very thin at the top and a few millimeters thick at the bottom. The solution was flowed drop-wise into the thin top of the adsorbent wedge, and broad zones of separated material were noted. This method is claimed to be very useful in the analysis of biologic substances where only small quantities are available, and was found to be more satisfactory than other micromethods in the analysis of certain biologic substances.

The Moving Boundary Method

This is a method that makes use of differential diffusion of ionized substances in an electric field, to effect separations. It was first developed by Lodge¹⁹ as a means of measuring directly transference numbers and ionic migration velocities. "Lodge's apparatus consisted of an horizontal glass tube 40 cm long, bent vertical at each end so as to dip into beakers. A solution of sodium chloride containing a small amount of phenolphthalein and slightly alkaline with sodium hydroxide, was made into a jelly with gelatin, and the mixture allowed to set in the glass tube. In one beaker a platinum cathode was placed and a solution of cupric chloride poured in. The anode was of carbon and the anode liquid hydrochloric acid. The apparatus was allowed to stand for twenty-five hours to measure the effect of diffusion. The progress of the hydrochloric acid was rendered visible by the decolorization of the pink gelatin, that of the copper chloride by the bluish turbidity due to the interaction of the copper salt with the small amount of alkali present, forming copper hydroxide. The following day the speed of diffusion was noted, and a potential difference of 40 volts was impressed upon the electrodes. The decolorization now proceeded from both ends at unequal rates, the hydrogen ion reacting with the indicator directly, and the chlorine discharging the color by combining with the sodium ion of the alkali."²⁰

James Kendall and students^{20, 21, 22, 23} were the first to make extensive use of this technique for effecting separations. In general, different ions move with different velocities under a potential gradient. Thus, if a solution containing a mixture of two electrolytes having the same anion but different cations is placed in a long horizontal tube and electrolyzed, the two cations would be expected to move toward the cathode at different rates. If remixing by ordinary diffusion can be minimized, a separation of the two cations is possible. These workers incorporated their solutions into agar-agar gels to obtain rigidity and to reduce ordinary diffusion. It was observed that, while diffusion in these gels was indeed greatly reduced over that in water, the colloid had negligible effect on the speeds of electrolytic migration of the ions. They considered the agar inert with respect to their electrolytic process, but in the light of later knowledge about selective adsorption on gels it seems possible that some of their anomalous results might be explained by adsorption effects.

The Kendall method used a modified Lodge apparatus. The mixture to be separated was in a narrow section of agar gel formed in the tube near the opposite end of the apparatus from that to which the ions would travel under electrolysis. Behind this was gel containing an ion inherently slower than those to be separated, and in front of the sample, gel containing a faster ion. Upon electrolysis, if the concentrations had been properly adjusted, the ions in the sample section moved slowly toward the appropriate electrode, the section remaining constant in length and the boundaries sharp. At the end of the run the portion of the gel containing the sample was removed from the tube and sliced into sections, which were examined for evidence of separation. Or the gel containing the mixture could be run through the apparatus one or more additional times if this was considered necessary to obtain a separation. In some experiments the total length of run was as much as 100 feet.

Among the mixtures that were separated more or less completely by this method were iodide and thiocyanate, barium and calcium, barium and strontium, chloride and iodide, yttrium and erbium, gadolinium and samarium, praseodymium and neodymium, radium, barium and mesothorium, and certain isotopic mixtures.

As was pointed out, the role of adsorption in the Kendall form of the moving-boundary method was generally negligible, in contrast to electrophoretic chromatography, in which it is an important factor. Possibly these two techniques might be profitably combined for inorganic separations. It would appear that if, in the moving-boundary method, some substance were used in place of the agar that selectively adsorbed one of the ions, this would in effect widen the difference between the mi-

gration velocities and facilitate a separation. Lange and Nagel,²⁴ in a short note published in 1936, proposed that the chromatographic method be tried for separating mixtures of rare-earth salts. There is nothing in the literature to indicate that these authors or others have acted on this proposal. The present writer intends to attack this problem by a combination of the two techniques as indicated.

Electrography

In this technique the adsorbent properties of cellulose fibers in filter paper are utilized to obtain distributive patterns or "chemical maps" of the distribution of certain materials on the surfaces of conducting specimens. A square of filter paper is impregnated with an electrolyte (such as sodium nitrate or chloride) and a reagent for the metals to be detected (such as antimony sulfide for copper, silver, etc.), or with a compound like sodium carbonate that serves both purposes. This prepared paper, moistened, is sandwiched between the specimen surface and a plate of inert metal, and the assembly pressed firmly together. A small current is now passed between the two metals, the specimen surface being made anodic. Ions from the specimen are electrolyzed into the paper, where they are immediately fixed as reaction products which are adsorbed on the cellulose fibers. Lateral diffusion or "bleeding" is minimized, so that the distributive pattern of the reaction products on the print corresponds to that of the metals tested for on the specimen surface. If desired, the print can be further "developed" by immersion in reagent solutions that form new reaction products of greater color contrast or permanence.

This method has been used extensively in the writer's laboratory for such purposes as rapid identifications, study of metallic inclusions in surfaces, testing plated surfaces for porosity, etc.³⁶ Its great advantage, besides those of simplicity and rapidity, is that one is enabled to determine not only what is present on the surface but how it is distributed.

The electrographic method was published simultaneously and independently in 1929 by Glazunov and Fritz. The interested reader is referred to the excellent review paper by Jirkovsky,³⁷ and to the paper by Yagoda³⁸ which not only reports some of that author's original work on biological material but contains a complete and up-to-date bibliography.*

Spot Tests

The well-known Feigl spot-testing technique may be carried out either with or without the aid of adsorbent media like filter paper. When paper is used, the sample drop is placed thereon, where it is allowed to spread uniformly by capillarity until the surface forces are balanced. The wet area is then treated with a drop of reagent, and an identifiable colored product is produced. Feigl's book³⁹ discusses the theory and practice of these tests, and gives complete directions for carrying out several hundred of them.

Clarke and Hermance⁴⁰ contributed two new ideas to this technique. By the use of a specially designed capillary burette, the rate of flow of the sample solution into the impregnated paper was controllable. With this it was found possible to restrict to a minimum the area covered by the reaction product, by providing that the rate of flow did not exceed the rate of reaction.

This increased the sensitivity of the tests, because sensitivity is determined by the smallest quantity of reaction product per unit paper area that the observer can just detect. These workers pointed out, however, that "if the precipitating agent

* The present writer, in collaboration with H. W. Hermance, has in preparation a monograph tentatively entitled, "The Application of Impregnated Papers to Microanalysis," to be published by Interscience Publishers, Inc., New York. In this will appear a full presentation of the authors' original work in electrography as well as in other techniques employing adsorbent media in analytical reactions.

contained in the paper is soluble in the solution under test, effective, uniform fixation of the reaction product is often delayed or entirely prevented. As the solution flows into paper so impregnated, the first portions react with the soluble reagent, producing a small quantity of colored product. The clear liquid, its reactive ion or ions thus removed, spreads outward carrying with it much if not all of the impregnant, depleting the area around the point of entrance. Hence the next portions of solution will remain unprecipitated until they are brought into contact with the reagent, concentrated by evaporation, at the periphery of the wet area. A further disadvantage of many soluble impregnants is their instability. Many soluble alkali salts decompose rather easily in paper, while less soluble salts of other metals keep reasonably well."⁴⁰

These considerations led to the use of reagents for paper impregnation that are slightly rather than readily soluble, *e.g.*, cadmium or antimony sulfide instead of sodium sulfide. The concentration of the reactive ion can be regulated automatically by proper selection of the impregnating salt, and the specificity of the test greatly improved by thus restricting the number of possible reactions.

Using their modified spot-testing technique, Clarke and Hermance were able to obtain hundredfold increases in sensitivity in some cases. They also effected differential precipitation of two or more solutes, in the form of concentric rings about the point of entrance of the drop into the reagent paper, the rings being analogous to the bands of a chromatogram.

A Method of Applying Reagent Papers to Large Volumes of Solutions

The spot test deals with drops of solutions. But there arises in microanalytical laboratories the problem of separating from much larger volumes of solutions metallic ions present in low concentrations. Clarke and Hermance⁴¹ describe a method for achieving this by the use of their principle of low-solubility reagents. Their method is to percolate a sufficient volume of the solution at a slow rate through a flange assembly that holds a disc of impregnated paper across the liquid stream. Three fundamental requirements must be met:

- (1) The impregnant must be sufficiently insoluble to withstand the action of the large volume of solution flowing through a small area of the paper.
- (2) Sufficient difference must exist between the solubilities of reagent and reaction product to ensure reasonably quantitative precipitation of the ion sought.
- (3) The reaction product must be capable of immediate fixation on the fibers of the paper.

A theoretical analysis of this method indicates that it should be capable of very complete separations. Thus it is calculated that, when separating traces of copper from a solution by percolation through cadmium sulfide-impregnated paper, even though the rate of flow is such as to allow the solution flowing through the disc to attain only 1 per cent saturation with cadmium sulfide, the copper remaining unprecipitated will be only 8.3×10^{-12} microgram per liter.

Future of These Methods of Analysis

Forces of diffusion and adsorption are active in most of the operations of chemical analysis. Sometimes they give rise to unwanted phenomena, such as occlusion. The techniques described in this paper have developed from the premise that, since these forces exist and cannot be avoided, they should be deliberately harnessed to useful purposes. One can say, in general, that the more we learn about the fundamental nature of diffusion and adsorption, the wider and more varied will be the analytical applications of these phenomena. But there is very much of these fundamentals yet to be learned. Paper, for instance, has proved to be a most useful and versatile adsorbent, but the mechanism by which it retains substances is by no means

clear. Freundlich¹¹, pp. 288-9 states that adsorption on cellulose is a pure ion-exchange reaction, and concludes that it is not the cellulose itself but rather the impurities like calcium salts that determine adsorption. This view is not accepted in all quarters, however. Comparatively little study has been made of other media than paper (except, of course, in chromatography). Undoubtedly such studies will receive emphasis in the future. The writer feels that an important future trend in these techniques will be the increasing employment of capillarity and electro-capillarity.

Finally, many other applications of these phenomena to analysis can and will be made, even with the theory in its present state. These developments are retarded by the fact that each is a problem in laboratory manipulation. Such problems cannot always be solved by systematic attack, but must await something akin to inspiration.

Colloid Chemical Aspects of Photographic Development

S. E. SHEPPARD

Research Laboratory, Eastman Kodak Co., Rochester, N. Y.

There can be no such thing as a colloid chemical theory of photographic development. Rather do we meet in the varieties of this process certain colloids or colloidal systems, and the particular chemico-physical characteristics thereof. Such are modifications of the properties of solids produced by extremely fine subdivision, the associated effects of increased surfaces and interfaces, processes of swelling and membrane potential formation, the rôle of phase boundary potentials, both as rigid Helmholtz double layers, and as diffuse double layers (ψ - and ζ -potentials) and the effects of these upon reaction velocities. The essence of photographic development seems to be that a "latent image," an invisible impression of varying amounts of light upon a material substrate, should be made visible by a subsequent physical or chemical process. The French term "révélation" is just the word for this perception of the matter. It is qualitatively adequate, but quantitatively incomplete. The fact is, that quantitatively, development is essentially what we would describe in these days of radio technics as amplification. An extremely minute chemical change is amplified or magnified many times by a subsequent process. Also, to an increasing extent with the degree of amplification, the gain in power is made at the expense of exactness in rendering of definition, or minute representation. In colloid chemical terms, development consists in reducing the dispersity, or increasing the particle size, of the so-called "latent image," at any rate for all processes with silver salts. The application of the term "development" to processes with bichromated colloids is practically justified, but technically inexact; what happens is more nearly analogous to "fixation" in photographic processes with silver salts, that is the removal of material not affected by light.

It is not necessary that we should deal in advance with the formation of the latent image in, or mostly on, the silver halides. It must suffice to say that it is generally agreed that this consists chemically of ultra-ultra-minute specks of metallic silver on, and to some extent in, the grains of silver halide. In gelatino-silver halide emulsions, it appears fairly certain that these latent image nuclei are formed upon preëxisting "sensitivity specks" of silver sulfide. We shall return to this in connection with gelatino-silver bromide emulsions, but let us first glance at that prototype of photography termed after its originator, daguerreotype. Was daguerreotype a discovery or an invention? Certainly chance, "*sa sacrée majesté, l'hasard*" counted for much in its inception, as Frederick II of Prussia said of other things. That Daguerre experimented with silver plates fumed with iodine was due probably to his association with Nicéphore de Niépce and the latter's more consistent and persistent efforts to invent a process of photo-mechanical reproduction. But what a chance that Daguerre should have put away an insufficiently exposed plate in a darkened cupboard with some mercury! Thus happened the "discovery" of the latent image by its development.

What occurs in daguerreotype is as follows. The silver iodide film is decomposed by light to give silver and iodine, the latter being taken over by the under-

lying silver plate to form more silver iodide. With short exposures to light, the amount of silver is too minute to be visible. However, the vapor of mercury condenses upon and magnifies these silver embryos, producing a visible image. It was appropriate in this, so to say, alchemical forerunner of photography, that "enobling" was effected by a further deposition of metallic gold upon the developed image. In contrast to this alchemical history or mystery, is the fact that it offers an interesting example of Langmuir's¹ fundamental theory of adsorption from the gaseous state. The mercury atoms which collide with unchanged silver iodide have "no abiding city"—the collisions are quasi-elastic and they return to their gassy chaos. But those that impinge upon the metallic silver particles of the latent image are held, and hold more of later comers, until a perceptible image is formed. How large must be an original silver nucleus: (i) to maintain itself; (ii) to hold incident mercury atoms? In the related case of sputtered metal (*e.g.*, silver) atoms upon a glass plate *in vacuo* Reinders and Hamburger² have argued for a nucleus of three or four silver atoms. The calculations of H. S. Taylor, H. Eyring, and A. Shérman³ on "The Binding Energies in the Growth of Crystal Nuclei from Metallic Atoms" rather indicate that two atoms within a certain interval (a primitive twin) should be sufficient. We do not know whether the answer "by Gemini" is correct, and the problem as to the smallest size of a latent image nucleus has carried over into the modern theory of the gelatino-silver halides.⁴ The "heavenly twins" may even be a single silver atom adsorbed to a silver ion—an immobilized atom as proposed by E. R. Bullock.⁵ At any rate daguerreotype affords this interesting connection with a fundamental colloid chemical problem, that of adsorption from the gaseous state.

In "wet plate" collodion, the silver support of daguerrotype was replaced by collodion on glass, and mercury vapor development by "physical" development with silver nitrate solution and a reducer. The silver nitrate came from the sensitizing solution for the iodized collodion, and the reducer was either pyrogalllic acid (acidified with acetic or citric acid) or ferrous sulfate, slightly acidified.

It is probable that silver ions are adsorbed to the silver of the latent image and thus reduced *in situ* by the reducer. A number of recent investigations⁶ of the reduction of silver ions (in solution) indicate the adsorption of silver ions to an effective solid surface (*e.g.* gold, silver sulfide) as an initial step, followed by adsorption to silver metal as soon as available. In consequence, these reactions show marked catalysis by silver nuclei, and it is this that the development of the latent image illustrates. In "wet plate" collodion, and again in collodion dry plates, an essentially colloid* medium appears, viz. collodion. This is an incompletely nitrated cellulose very soluble in mixtures of about 50:50 ethyl alcohol and ethyl ether. These solutions on evaporation give clear transparent films of great strength and flexibility. They are insoluble in water, but can be made permeable to water and aqueous solutions.

This last property is very important for photographic use since it permits access or penetration of developers and fixing agents. Permeability would continue more or less so long as the film was still swollen with residual solvent, but on loss of this the collodion became "horny" and impermeable. Empirically, this was lessened by introduction into the solution or dope of various substances, generally hygroscopic, termed "preservatives." Examples are salts, such as magnesium nitrate, also honey, glucose and—as transitional to the gelatino-bromide dry plate—albumen. Some part of this technique overlaps with that employed in the preparation of collodion membranes of varying porosity, as for ultrafiltration.⁷

The reactions of silver ions in solution with various reducers have been the subject of recent important studies by T. H. James.⁶ His investigations have brought out the important rôle of colloid silver in affording an adsorption site for silver ions,

* From the Greek *κόλλα*, glue.

with further attraction of reducing ions followed by reduction *in situ*. In some cases, *e.g.*, hydroxylamine, *p*-phenylene-diamine, there may be more or less simultaneous adsorption of the reducer to the colloid silver.

The introduction of dry collodion emulsions of silver bromide, together with the application of alkaline organic developers by Russell⁸ paved the way for the replacement of collodion by gelatin.⁹

We shall defer for later notice the specific colloid chemical behavior of gelatin in relation to development. For the moment it must suffice that its ability to swell in water and aqueous solutions while remaining an elastic gel, allows a variety of reactions to occur between dissolved reagents and the solid silver halide. As to this, in *negative* emulsions, we have to deal with a suspension of silver bromide crystallites, containing some two to five per cent silver iodide, and ranging in size from *ca* 0.3 μ to 3 μ . In *positive* emulsions we have more generally crystallites of silver chloride or chloro-bromide, of a greater dispersity, *ca* 0.05 to 0.3 μ , or in some cases of silver bromide alone, of comparable dimensions. It is not, however, with the practice of photography that we have to deal, but with certain aspects of the theory of one phase of it.

After the formation of a latent image there is employed today almost exclusively an alkaline organic developing solution. For the chemical constitution of these developers reference must be made elsewhere.¹⁰ Shortly after the introduction of gelatin plates, there was considerable use of Carey Lea's ferrous oxalate developer. This, together with certain other "inorganic" developers is now only of scientific interest. Their great importance for the theory of "chemical" development, as the direct reduction of silver halide grains is termed, in contrast to "physical" development employing solutions of silver salts, is that they have practically no greater solvent power than water itself. The alkaline organic developers in practice contain quantities of sodium sulfite, from 5 per cent upward, which can dissolve silver bromide to an extent increasing with concentration. However, except in the higher concentrations, this solvent power is of secondary importance compared with its intervention in the purely chemical aspect of development as a preservative. Its other potentiality as a silver halide solvent will be dealt with later. We may consider, therefore, that in normal chemical development the activity of silver ions in solution is very small, as instanced by the following figures * for 25° C.

| | | |
|-------------|------------|--|
| Water | pAg = 6.08 | $S = (8.3 \times 10^{-7})^2$ |
| 0.001 N KBr | " = 9.16 | and $C_{Ag^+} \times C_{Br^-} = \text{constant}$ |
| .01 N KBr | " = 10.16 | |

$pAg = -\log C_{Ag^+}$, where C_{Ag^+} = concentration of silver ions. Hence $pAg = 6.08$ indicates a concentration of silver ions = 8.3×10^{-7} , which is the solubility of the AgBr in water at 25°C. S = solubility product. This equals $C_{Ag^+} \times C_{Br^-} = \text{constant}$.

Photographic emulsions usually contain sufficient excess of bromide ions to be considered, when swollen with water, as at about pAg 8. Further, many photographic developers have sufficient bromide included to keep the concentration of free silver ions at about this figure. It will be seen that the free silver ion concentration must be extremely low. None the less, early hypotheses as to the mechanism of chemical development, under the spell of the "physical chemistry" of Ostwald-van't Hoff-Arrhenius were subservient to the adage "Corpora non agunt nisi soluta"—by which was understood, aqueous solution. This had its points, but only van't Hoff was already indicating the existence of solid solutions. Without too much thought as to the extraordinarily small concentrations of silver ions possible, only a reaction in aqueous solution was considered. It was supposed that in this phase reaction oc-

* From A. Moyse, A. Ballard and S. E. Sheppard: Unpublished work from the Eastman Kodak Research Laboratories.

curred between dissolved silver ions and the (organic) reducer according to such an equation as

or, for such semi-inorganic reducers as ferrous oxalate

and such inorganic ones as hydroxylamine

As stoichiometric equations, these express the economics of the process, but actually give no indication of the mechanism. In this matter, it was supposed that a super-saturated solution of atomic silver is formed, which then deposits silver locally upon the latent image nuclei. This was considered to occur the more readily, the larger the nuclei. In connection with this there was stressed the conception of equilibrium or reversibility in development. This could, in fact, be demonstrated for the ferrous salts, and imputed *de jure* to organic reducers such as hydroquinone—although, in fact, it was evidently of vanishing moment for these substances. And its entire absence in the case of NH_2OH , (hydroxylamine), and some kindred reducers, was quite overlooked. None the less, an important rôle was assigned to the redox potentials of developers.¹¹ The influence of bromide ions on development was ascribed to their ability to reduce the concentration of free silver ions, according to the mass law $[A\ddot{g} \ B\bar{r}] = \text{constant}$, and thereby the free energy of the reaction $A\ddot{g} + \bar{R} \rightleftharpoons Ag + R$. Hence it was deduced that the *relative* redox potentials of developers might be ascertained from the effect of bromide ion in depressing the density developed in unit time.¹¹ In the case of true equilibrium in development, which can be approached in the case of ferrous salts, these considerations have a certain weight. But with the usual organic reducers, development is not a reversible reaction.

It was W. D. Bancroft¹² who first expressed scepticism of the importance of an equilibrium in ordinary photographic development. He suggested that adsorption of the developer to the silver bromide grain is the essential thing. Provided that the "latent image" could be reduced more easily than the remaining silver halide, one obtained a *negative*, whereas if the unaffected silver halide were more easily reduced, as he supposed to occur with certain reducers, a *positive*. This corollary is a purely *ad hoc* interpretation, and disregards the evidence that the latent image consists itself of silver. None the less Bancroft first rescued the process from a watery grave. The idea of an adsorption was proposed in a more explicit fashion by Sheppard.¹³ He suggested that the reducer, which is usually an anion, is adsorbed to the silver halide, forming a metastable complex or salt of silver. At the interface between the silver speck of latent image and the silver halide the complex decomposes giving an atom of silver to the nucleus. Certain experiments independent of development were produced in support of this conception, but it could not be regarded as conclusive. A change of ground was proposed by A. J. Rabinowitsch.¹⁴ He suggested that the developer is adsorbed to the metallic silver nucleus itself, and with S. Peissakhovitsch¹⁴ proffered experiments indicating adsorption of hydroquinone to colloid silver. The experiments of Rabinowitsch and Peissakhovitsch were repeated by Perry, Ballard and Sheppard.¹⁵ They showed that the experimental error of the Russian investigators, consequent on not removing oxygen from the system, was much too great for their conclusions to be accepted. Actually, Perry, Ballard and Sheppard failed to calculate the degree of unimolecular adsorption possible under their experimental conditions. This will be done now to give an approximate idea of the possibilities.

The particle size of the silver sol was estimated from electron micrograms obtained by Mr. A. L. Schoen,* taken at 25,000x magnification. Micrometric readings were made on prints at a further optical enlargement of 3 to 4 times. The readings were made for about 100 particles. The diameters varied between 10 μ and 40 μ , the arithmetical mean being 20 μ . Assuming the particles to be cubic, and the measured diameter that of the diagonal, from the size-frequency distribution, the total area of all class-sizes gave an average diameter of 202 Å, which is very nearly that obtained for the arithmetic mean, *viz.*, 200 Å. The surface area of 100 particles was calculated to be 8.2×10^6 Å². These values are subject to error from several sources. The number of readings was insufficient to give a good size-frequency estimation. Some agglomerates were observed in the electron micrographs, but it is not possible to say whether they existed in the sol, or were formed in the preparation for the electron microscope. Hence they had to be neglected.

From the radius of the silver atom ($r = 1.44$ Å) or a distance between centers in the surface of 2.87 Å, it is readily calculated that the number of silver atoms on the surface of the average particle is 1.20×10^4 . According to the estimate of size, the specific area per grain is 4.9×10^5 cm². Again, the amount of silver per liter of the sol was 0.68 grams, corresponding to 4.1×10^{18} particles per liter, or to 5.2×10^{20} surface silver atoms.

The experimental data showed 1.03×10^{-4} equivalents of hydroquinone unaccounted for per liter, *i.e.*, 6.2×10^{19} molecules. Hence, the ratio of hydroquinone molecules not accounted for to the number of surface silver atoms is $\frac{6.2 \times 10^{19}}{5.2 \times 10^{20}}$, or approximately 1/10. However, the hydroquinone molecule is much larger than the silver atom, and would "cover" several if monomolecularly adsorbed.

Calculation of the van der Waals' area of the projection of a dihydroquinonate ion (i) lying flat, (ii) oriented edge-on, (see Fig. 1) gives for the former (more

FIGURE 1. Van der Waals' projective areas of the dihydroquinonate ion (i) flat, (ii) oriented edge-on.

probable) orientation 43 Å², for the latter 35 Å². From this, and assuming *irreversible* adsorption, *i.e.*, total adsorption, one hydroquinonate ion could cover about 7 silver atoms when flat, or about 5.5 edgewise.

If *all* the hydroquinone not accounted for in the analyses were adsorbed, this would allow about 84 per cent coverage for flat molecules, or about 60 per cent, with edgewise molecules. However, the discrepancy was actually close to the experimental error.

Consequently, it has not been demonstrated that an unimolecular adsorption may

* Of the Eastman Kodak Research Laboratories.

not occur to some extent, whether on colloidal silver or colloidal silver sulfide, but it is equally probable that the amount possibly was consumed by residual oxidation.

Thus the question is not decided, and further experimental work is required. It is, moreover, decisively important in respect of a hypothesis of chemical development advanced by Gurney and Mott.¹⁶ According to these authors, developers are substances, donors of electrons, the levels of which must be higher than the electronic levels in silver or silver sulfide. There is supposed to be some difference in the electronic levels in minute specks of silver, such as the latent image, the levels being lower, up to a point, as the speck is larger, and conversely. It is supposed further that the reducer attaches itself (is adsorbed) to the silver speck, charging it with its electrons. Thereby the speck tends to acquire a negative charge on the face remote from the developer. This face attracts silver ions of the lattice of silver halide in which the speck is imbedded; these are neutralized by the electrons of the hinterland, becoming as silver atoms part of the growing silver lattice. Schematically, the mechanism is indicated by the following diagram:

This indicates what is supposed to happen at the two interfaces. On the left hand side of the silver speck the reducing ions move up and are adsorbed to the silver, to which they contribute electrons. At the right hand side these accumulate on the rear face of the silver speck, where they attract interstitial silver ions from the solid silver halide in contact with the silver speck. These they neutralize, forming silver atoms which build on to the silver crystallite, and *da capo*. A less schematic and more topographic version of this hypothesis is shown in Figure 2, due to Dr. J. H. Webb of the Eastman Research Laboratories.¹⁷ This is a very attractive picture of the mechanism of development, especially in respect of its continuity with Gurney and Mott's theory of the formation of the latent and visible images by a similar process. It has particular interest for colloid chemistry, in suggesting a mechanism for catalysis at interfaces.

In specific regard to development, the accretion of silver atoms at the rear interface Ag/AgBr has been supposed to develop a reaction pressure pushing the speck outward into the developing solution. This could provide an explanation of the observations, discussed in more detail later, that in the early phases of chemical development, protuberances and even filamentous processes may be seen—or rather photographed—to have been produced beyond the surface of the silver halide grain. It is true that the specific volume of silver metal is *less* than that of silver halide which it is replacing, and that the halide ions remaining from the reduction must go out into the solution, leaving void spaces to the rear of the speck. These considerations reduce the probability of a pressure occurring as suggested; there is also the fact that extra-granular protuberances do not appear to be an inevitable aspect of development, since it is possible for development to be effected¹⁸ so that no protuberances are formed, the crystal maintaining its shape, giving a slightly shrunken pseudomorph. It has been suggested, however, by adherents to this hypothesis—one is tempted to term it the Januarian or two-faced hypothesis—that it provides an explanation of the infra-granular filamentous proliferation of the reduced silver in chemical development, as revealed by the electron microscope.¹⁹ We shall come to speak of this in due course.

There is one factor which argues rather strongly against this hypothesis. Other things equal—same developer, same temperature, etc.—the rates of development should depend upon the mobility of silver ions in the respective crystals. The rates should be, therefore, in the order $\text{AgI} > \text{AgBr} > \text{AgCl}$. Now photographic experience has long opted for the reverse order of developability. Recent experiments of S. E. Sheppard and C. L. Graham²⁰ have shown that the relative rates of development under as nearly identical conditions as possible strongly indicate the order

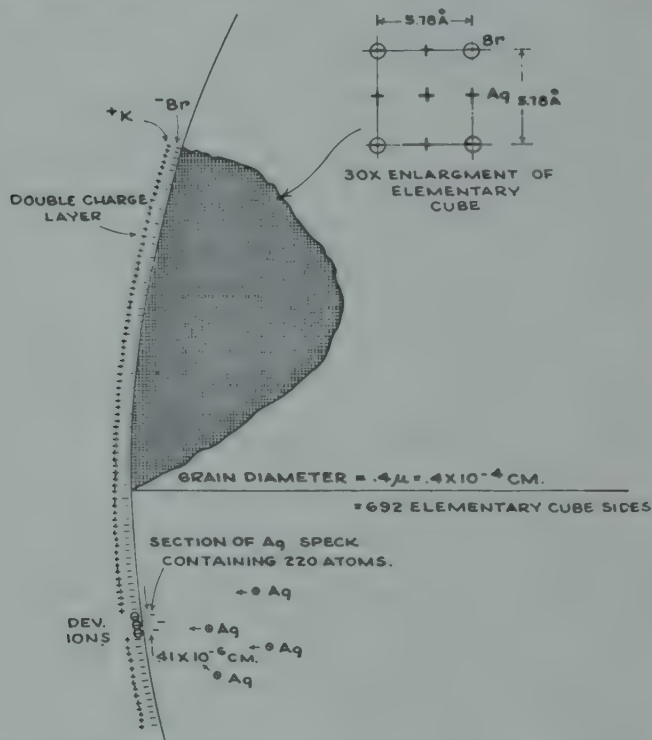

FIGURE 2. Schematic model of an exposed grain and latent image speck, illustrating Gurney-Mott hypothesis of development (according to J. H. Webb).

$\text{AgCl} \leq \text{AgBr} \gg \text{AgI}$. The mobilities will be proportional to the electrolytic conductances since the evidence is that only the silver ion conducts in these crystals, and the movement is supposed to be directed by the electric field of the speck. Values for these conductances are given in the following table:—

Table 1
(Specific Conductivities in mhos)

| Silver Halide | Conductance at 26° C. S. I. | Conductance at 25° C. S. S. | Observed Range of Transition from S. S. to S. I. |
|---|--|--|--|
| AgI | 4×10^{-7} to 8×10^{-7} | 4×10^{-7} | None |
| $\text{Ag}(\text{Br})(\text{I})$ 1 to 5% \mp | 1×10^{-4} to 1×10^{-7} | 1×10^{-4} to 1×10^{-5} | None |
| AgBr | 5×10^{-5} to 1×10^{-7} | 0.5×10^{-7} | 20° C. to 0° C. |
| AgCl | 1×10^{-10} | 3×10^{-7} to 1×10^{-7} | 100° C. to 200° C. |

It should be explained why to these substances there might be imputed more than one conductance at the same temperature. This depends upon whether the crystal is presented in a condition approaching the ideal lattice, or, broadly speaking, as an imperfect crystal. In the former case (S. I. = structure insensitive) the conductance

has a more constant and reproducible value, and work has to be done both to get a silver ion out of the lattice into an interstitial position and to mobilize the interstitial ion. In the S. S. (structure sensitive state) the work function may refer chiefly to mobilization of interstitial ions; although in this latter case it is possible that we are not solely concerned with the relatively simple contrast of order: disorder, where the disorder is of the Frenkel type. This means that in the disordered system, only strayed Ag^{\ddagger} ions are involved.²¹ It is possible that we are concerned in the S. S. state—qua state—with lattices, or orders, of more open type, *i.e.*, of somewhat higher energy.

It has been calculated by Webb²² from purely photographic data* that the mobility of silver ions in the silver iodo-bromide crystals of ordinary negative photographic emulsions corresponds to that of S. I. silver bromide. That is to say, he concludes that the temperature coefficient of the mobility over the range from 50° C to -72° C accords with that for the S. I. type. This does not seem to agree too well with the direct electrolytic conductance measurements. However, should this be the case, and for the other halides, that is, should their crystals in gelatin emulsions be of the S. I. type, evidently we have a rather flagrant disagreement with the Januarian hypothesis in respect of the order of developability. On the other hand, should it be concluded that the grains are of the S. S. type for silver bromide, iodo-bromide, and iodide, this could hardly be the case for the chloride, according to all the measurements available. In fact, in any case, the actual order of developability disagrees definitively with that deduced from direct measurements of the conductivity.

It has been suggested²³ that in view of the rapid and localized nature of chemical development, the heat produced by the exothermic reaction $\bar{\text{R}} + \text{Ag}^{\ddagger} \rightarrow \text{R} + \text{Ag}$ may count for something in the actual process, that this may tend to become adiabatic rather than isothermal. There is much to say for this as an operative factor. However, the "heats of activation" of silver ion mobility derived from the temperature coefficients of electrolytic conductance are as follows:

| AgI | S. S. | S. I. |
|-----------|------------------|------------------|
| AgBr(I) | (10)k. cal./mol. | (10)k. cal./mol. |
| (1 to 5%) | 5 to 7 | |
| AgBr | 6 to 9 | 14 |
| AgCl | 7 to 9 | 20 |

If the grains are S. I. crystals, the same heat of reaction (in development) should produce a much greater acceleration for AgI than for AgBr than for AgCl, which is again contrary to the order of developability. If they are of S. S. type, there should be approximate equivalence for AgCl and AgBr, with perhaps some disadvantage to AgI, but hardly sufficient to explain the low developability of this. Moreover, the actual temperature coefficients of development velocity depend considerably upon the developer used, and bear little relation to the temperature coefficients of silver ion mobility in the silver halides. Hence, one may conclude at present that this latter can play but a small part in chemical development.

None the less, the evidence is strong that the classical model, reduction of silver ions in aqueous solution followed by deposition of silver on the "latent image" nucleus, is entirely inadequate. The process has this definite colloid chemical aspect, it seems to be essentially a reaction at the interface of solid and solution.

Retarding and Inhibiting Barriers

Thus far we have considered photographic development without notice of the most obvious colloid concerned, *viz.*, the gelatin in which the silver halide crystals are suspended. Let us retrace our steps to the beginning. In the earliest phase, gelatin has to absorb water and developing solution, and swell.

* From the effect of temperature on the high intensity reciprocity failure.

The swelling of gelatin in liquid water involves at least three processes, *viz.*: (i) Adsorption of water molecules to the gelatin macromolecules. This corresponds to the early stage of the sorption of water vapor by gelatin.²⁴ (ii) Release of orientation (strain)²⁵ of gelatin macromolecules and increase of entropy—a process involving a Joule effect similar to that observed on heating stretched rubber. This process—elastic swelling—occurs in the latter stages (high humidities) of vapor sorption. (iii) Adjustment of the ampholyte to the pH of a solution, with development of Donnan membrane equilibrium, giving excess swelling over that of isoelectric gelatin according as the pH departs from the isoelectric point.

FIGURE 3. Swelling of gelatin in water as a function of pH.

The usual organic developing solutions are quite alkaline, \sim pH 11. As can be seen from Figure 3, gelatin in such solutions will tend to swell very considerably and indeed quite rapidly. This is, however, restrained by the presence of neutral salts, usually the sulfite and carbonate of soda of the developing solution, and on occasion, by the addition of sodium sulfate. The adjustment due to change of pH corresponds roughly to the process symbolized below:

In the alkaline solution the gelatin framework develops a negative charge. According as the reducing molecule is negatively charged or neutral, this will or will not occasion a barrier to its penetration.²⁶ This is not the only barrier protecting the silver halide from the attack of the reducer, as we shall see. The alkalinity or high pH of the medium, however, has a twofold effect: it charges the gelatin negatively, but at the same time the relative freeing of $-\text{NH}_2$ groups of the gelatin enables these to coordinate with silver ions, as shown on titrating gelatin electrometrically with silver salts (cf. Fig. 4). This involves a lowering of silver ion activity, and therewith of reducibility. Considerable of the "protective" action of gelatin is no doubt due to this. It is limited, however, in ordinary photographic emulsions by another factor, namely, the excess of bromide ions usually present.* This will tend to restrain the amino groups from coordinating with the silver ions of the silver halide.

The negative charge on the gelatin will tend to hinder and restrain the entry of negatively charged reducing ions into the emulsion layer, as has been definitely

* The pAg of such emulsions is of the order of 8 to 9.

FIGURE 4. Combination of silver ions with gelatin as a function of concentration of silver ion and of pH; curve on right for pH 5; curve on left for pH 9.

shown to occur for negatively charged dye ions.²⁶ Although the molecular weight of such dyes exceeds that of the usual developers somewhat in the ratio of 4 to 1, the barrier must exist to some extent in the latter case also.

The effect of such a barrier may be reduced or "swamped out" by adding a considerable concentration of neutral electrolyte, *e.g.*, sodium sulfate. This has been demonstrated in the dyeing of gelatin²⁶ and is perhaps in some degree the reason for the acceleration of development by neutral salts with certain alkaline developers, which was observed by Lüppo-Cramer.²⁷ However, the "potential barrier" constituted by gelatin for negative ions is only an outer barrier. There exists an inner barrier of more fundamental importance, consisting of adsorbed halide ions, and in our particular case, bromide ions. Some two decades ago, Lüppo-Cramer²⁸ directed attention to two important facts. Precipitated and well washed silver bromide is immediately reduced in darkness by ordinary photographic developers. On the other hand, a hydrosol of silver bromide, stabilized by slight excess of bromide ions, is only slowly reduced in darkness by the same developer, but rapidly after exposure to light. It is, as he put it, a model of a nonfogging emulsion. This striking difference between "gel" and "sol" forms of silver bromide was made the basis of a hypothesis of latent image formation and developability* by Ungar and G. Schwarz.²⁹ They suggested that the essential action of light consisted in discharging electrons from bromide ions, adsorbed to silver bromide, and forming a "barrier" layer. This allowed a developer to attack unprotected silver ions. Without much doubt this exaggerated the rôle of the barrier ions, totally neglecting as it did, the demonstrable importance of silver, and on occasion, silver sulfide, specks.³⁰ The essential importance of the barrier ions for the kinetics of development, rather than for the formation of the latent image, has been shown by James,³¹ in the first of the most searching and serious of recent investigations on development. In earlier studies on the kinetics of development³² the existence of a more or less marked "induction period" was deduced, as well as the fact that its magnitude depended upon both the nature of the developer and the concentration of bromide ions. This was interpreted, in terms of a thermodynamic equilibrium, as a period of *nucleation* consequent upon both the redox potential of the developer, and the active mass of the silver ion as controlled by that of the bromide ion (as we would say now, the p_{Ag}). This led to much work on the empirical estimation of the redox potentials of developers *via* their bromide depression coefficients, since developers, like humans, differ in respect of the depressing effect of a dose of bromide. James made clear that the supposed connection between bromide susceptibility and redox potential was entirely fallacious. Proceeding from the viewpoint of reaction kinetics rather than from that of thermodynamic equilibrium, he associated bromide susceptibility with the sign and the multiplicity of the electric charge upon the reducing entity. In an investigation of Staude's observation³³ that *quinone* catalyzes development by *hydroquinone*, James showed that acceleration by oxidation products is not a general effect for organic developing agents, nor even for a majority of them. For inorganic developers it was evidently not the case. Further, he showed that quinone catalysis cannot even account for the induction period in hydroquinone development. In his words, "The induction period has its origin in an entirely distinct kinetic phenomenon, involving the penetration by the developer ions of an electrical barrier at the surface of the silver halide grains."³¹ In support of this conclusion, James pointed out that "with some developers no induction period appears, with others a short induction period is present, and that with still others, the induction period is pronounced. A comparison of the curves obtained for all the developing agents tested reveals four distinct types. These types are not defined by the chemical nature of the developing agents, but rather by the *charge on the reducing ion or molecule*."

* Curiously enough, an equivalent difference between "sol" and "gel" forms of colloidal silver was suggested for latent image formation (developability) by F. F. Renwick.^{32a}

In Table II developing agents are grouped somewhat according to their chemical constitution (vertically) and (horizontally) according to the charge on the actual reducer.

Table 2
Classification of Developing Agents

| Chemical Series | Charge on Active Particles | | | |
|-----------------------|--|------------------------------|--|----------------------------------|
| | 0 | -1 | -2 | -3 |
| Hydroquinone | | | Hydroquinone | Sodium hydroquinonemonosulfonate |
| <i>p</i> -Aminophenol | | Elon | <i>p</i> -Hydroxyphenylglycine | |
| | | <i>p</i> -Aminophenol | Elonmonosulfonic acid | |
| <i>p</i> -Phenylene- | <i>sym</i> -Dimethyl- <i>p</i> -phenylenediamine | <i>p</i> -Aminophenylglycine | | |
| | <i>p</i> -Aminodiethylaniline | | | |
| | Diaminodurene | | | |
| | 2-Amino-5-diethylaminotoluene | | | |
| Others | | Hydroxylamine | Pyrogallol (Fe)(C ₂ O ₄) ₂ ⁻⁻ | |

Figure 5 reproduces James' characteristic curve for each charge group. "When the reducing agent is uncharged (group 0), there is no induction period. If the agent possesses a single negative charge (group -1), a small induction period appears. The extent of the induction period increases progressively as we pass to two negative charges (group -2) and to three negative charges (group -3). This behavior was observed with every agent tested, regardless of the chemical series to which the agent belongs. Group 0 contained only members of the *p*-phenylene-diamine series which, as we have observed, should not undergo significant acid ionization at the pH employed. Group -1 contains some of the *p*-aminophenols, a substituted *p*-phenylene-diamine which has obtained a negative charge by virtue of dissociation of the acid carboxyl group it contains, and the inorganic substance hydroxylamine. Group -2 contains hydroquinone, which, in the pH range employed, is active as the divalent ion, two members of the *p*-aminophenol group which have acquired an added negative charge by virtue of ionization of a carboxyl or sulfonic acid group, and potassium ferroöxalate.* The active ionic species of pyrogallol has not been definitely established as yet, but the curve of the pyro developer fits fairly well into group -2. Group -3 has as its sole representative sodium hydroquinonemonosulfonate." For further quantitative evidence validating his theory, we must refer to the original paper.

James then shows that the behavior of bromide ion, and of change of concentra-

* "This developer had the composition M/40 ferrous sulfate, M/5 potassium oxalate, and 0.1 g. potassium bromide per liter. The solution was buffered at pH 8.56."

tion of bromide ion, with different developers is consistent with this "potential barrier" theory. The respective parts played by a presumed rigid element of a Helmholtz double layer— ψ -potential of Freundlich and by a diffuse or Gouy layer—so-called ζ -potential—have afforded a fruitful field for debate in colloid chemical problems. It is very possible that it is fundamentally a matter of total (irreversible) and reversible adsorption respectively. In the case of bromide ions, adsorption as distinguished from integration in the crystal lattice, must be regarded as essentially reversible, although there are probably certain degrees of lattice surface stability.

FIGURE 5. Effect of charge of reducing agent upon shape of development curve.

- × Hydroquinone
- Δ *p*-Aminophenol
- Diaminodurene
- Sodium Hydroquinone Monosulfonate

The double layer for bromide ions and counter ions will, therefore, be of the diffuse type, and not the rigid type frequently illustrated (Cf. Fig 2). Owing to the mobile type of this adsorption, the rôle of the kinetic energy of the developer ions in penetrating the barrier, as postulated by James, becomes more plausible. This kinetic (ζ -potential) character of the bromide ion barrier is in agreement with the fact observed by Sheppard and Elliott³⁴ with a rather weakly alkaline (sodium carbonate) hydroquinone developer that agitation progressively reduced the induction period. It does this by washing out bromide ions into the surrounding liquid. The suggestion of an impeding or delaying rôle of negatively charged gelatin is quite consistent with and consequent upon James' theory of the rôle of bromide ions. Compared to these, its negative barrier function must be of minor importance. This is evident from the dominance of the bromide ion effect in photographic development. The gelatin barrier would be relatively *rigid*, and hence the smaller molecular weights of the developers would count in comparison with dyes. The "protective" colloid character of gelatin for silver halides towards all developers is, as previously stated, doubly a function of pAg , and indeed becomes decisively lessened for

$pAg < 6$ and for $pH < 6$. This is shown in the following figure (Fig. 6). This brings out two things. Spontaneous developability or "chemical" fog increases rapidly for pAg values < 6 , but also the amount is much greater the longer the time of keeping or of incubation of the emulsion layers. The latter effect indicates the acceleration produced by *silver nuclei* formed on incubation of the layers of low pAg . The correlative to these consequences of deliberately adjusting the pAg of emulsion layers is the frequently observed "fogging" effect of simple washing of photographic

FIGURE 6. Protective behavior of gelatin for silver halide toward developers as a function of pAg .

plates and films. In recent years the reduction of the activity of silver ion effected by excess bromide has been replaced or supplemented by various so-called "antifoggants" such as nitrobenzimidazol, benzotriazole, which form compounds of low solubility or of high complexity with silver ions. It is possible that their action is similar in some respects to that of dyes which lower the reducibility of silver halides³⁵ and that in particular they tend to react with the silver halide at its interface with the silver speck of the latent image,³⁶ an action which would constitute a still deeper barrier than that by bromide ions.

Oriented Adsorption

The adsorption of halide ions, *e.g.*, of bromide ions to silver bromide, is a reversible process, involving a kinetic equilibrium similar to vapor pressure. There is possible with certain substances adsorption resulting in static equilibrium, because the adsorbed ions or molecules are so *oriented* on adsorption that that part of the ion or molecule which allows hydration, the hydrophile part, is attached to the solid surface, while the part presented to the water is hydrophobe and incapable of hydration. The picture is essentially that introduced by Hardy,³⁸ Harkins³⁸ and Langmuir.³⁹ Certain dyes, notably the cyanine dyes used as optical sensitizers in photography, and many desensitizing dyes, have a structure, illustrated for the cyanine dyes in Figure 7. It has been shown by James⁴⁰ that the reduction of precipitated silver chloride by hydroxylamine proceeds in two phases, a non-catalyzed one and a catalyzed one—the latter corresponding to the "nucleation" of the halide with metallic silver. The rate of reduction in the non-catalyzed phase is proportional to the surface area exposed to the hydroxylamine. This is shown by the progressive diminution of the effective area on increasing the degree of adsorption of a selected cyanine dye. When saturation with the dye is reached, the rate of reduction falls to a steady minimum. The existence of a minimum, rather than complete inhibition, derives no

doubt from the size of the dye molecule, and the fact that it "covers," but does not neutralize, several ions of the surface.³⁷ Hence it leaves interstices through which the reducer can penetrate and react.

Gelatin behaves in a similar manner, but with a considerably higher minimum, indicating a still more open adsorbed layer. The similarity, however, is notable. It was shown by Sheppard and Sweet⁴¹ from experiments on the effect of gelatin on the interfacial tension between water and toluene, that gelatin must be attributed the double-edged * character of such molecules as the higher fatty acids, the soaps, many

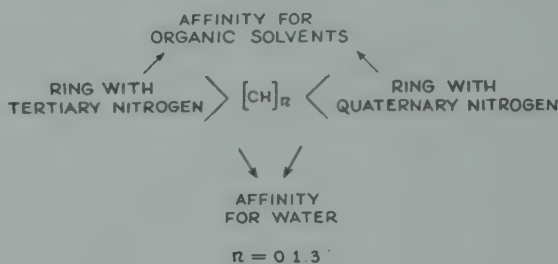

FIGURE 7. Schematic structure for cyanine dyes.

dyes. This has been confirmed recently in experiments on its adsorption to silver bromide. Probably because of the large size of the molecule or micelle, and the sparse distribution of the atom-groups attaching to the silver halide, the oriented adsorption layer is much more open, the "protection" even less complete than with dyes.

Both the basic cyanine dye and gelatin reduce the rate of reduction of *nucleated* silver chloride by hydroxylamine to minima, as in the case of the non-nucleated reaction. The behavior is consistent with the view that the reaction is between unprotected silver ions of the surface and the hydroxylamine,¹³ and agrees with the conception previously put forward.

Another example of "oriented adsorption" in relation to development is due to A. Lottermoser and R. Stendel.⁴² Proceeding from the Schwarz-Ungar hypothesis of developability by removal of negative charges at the surface, they tried the effect of surface-active negative and positive ions on the reducibility of silver halide sols, and on the development of gelatino-silver halides. As surface-active *anion* was used the sodium salt of duodecyl sulfuric acid ester— $C_{12}H_{25}OSO_3Na$ (abbreviated as C_{12}'), and as surface-active *cation*, the duodecyl-pyridinium bromide— $C_{17}H_{30}NBr$ (abbreviated as C_{17}'). These interesting experiments can be only briefly summarized. It was found with silver iodide hydrosols that in presence of the specified "surface-active" ions these alone determined the charge, irrespective of excess of silver or iodide ions. When positively charged silver bromide hydrosols were prepared with C_{17}' , they were immediately reduced by reducing anions, in agreement with the "barrier" theory. Furthermore, the development of photographic emulsions (developing-out papers) was strongly accelerated by C_{17}' , in the case of hydroquinone, definitely but less so for pyrocatechin, and for glycine but little. It is unfortunate that a (probably) uncharged reducer such as hydroxylamine was not tested. The work of James, with silver chloride, to which the cationic cyanine dye was adsorbed, showed that in this case, the rate of reduction was *lowered* by the adsorption of the dye. One would expect the same behavior for the duodecyl-pyridinium cation. The acceleration of development (of gelatino-silver chloro-bromide layers) in hydroquinone by C_{17}' is in accord with Lüppo-Cramer's discovery of the acceleration of development (in hydroquinone developers) by basic dyes, such as phenosafranin.

* G. S. Hartley has termed such bodies "amphipathic," but the term has a subjective implication. Perhaps "amphibolic" would be better.

Inhibitors

A good deal of the matter concerning inhibiting agents has been dealt with in the preceding sections. The conception of "inhibitors" nominally concerns substances which prevent or reduce "fog" in development, undesired "spontaneous" reduction of non-exposed silver halide grains. The use of bromide (halide) as a fog inhibitor did not lead to any extension of this category. The discovery by Lüppo-Cramer⁴³ of desensitizing dyes (consequent on his observation of the action of the oxidation products of certain developers, notably *amidol*, in protecting an emulsion against light during development) very possibly opened up this field. He found that many basic dyes, *i.e.*, cations, inhibited the formation of new "latent image" during development. By no means all dyes of this type are practically useful, and the theory of their action is not fully understood. However, it may be stated that fundamentally the dyes in question are such as have a definite redox potential sufficient to oxidize nascent silver—or its equivalent*—of a latent image. It is a curious fact that Lüppo-Cramer himself vacillated between two hypotheses as to their action. He proposed first an "oxidation" theory in accord with the foregoing statement, then a hypothesis of "nucleus isolation," according to which the dye was adsorbed chiefly at the interface between silver nuclei of the latent image, and silver halide.⁴⁴

In 1927 Sheppard and Hudson⁴⁵ discovered the inhibiting action (upon development) of the thioanilides. These substances have no oxidation potential, and their action was interpreted in terms of Lüppo-Cramer's hypothesis of nucleus isolation—it was supposed that they were adsorbed at the interface between latent image silver and silver halide⁴⁶—forming difficultly reducible complexes with silver ions. They were the precursors of a considerable multitude of "fog inhibitors," organic compound forming silver compounds of lower reducibility than silver halide.

It is generally characteristic of these substances that an optimum concentration is soon reached, beyond which not only is "fog" inhibited, but the developability suffers, with consequent lowering of photographic sensitivity and speed.⁴⁵ As an example, the following data obtained with nitrobenzimidazol added to a *p*-aminophenol developer⁴⁷ may be cited:

Table 3. Action of Nitrobenzimidazole in m/20 Developer

| Development Time in Min. | Developer Fog at a Concentration | | | |
|--------------------------|----------------------------------|--------|--------|-------|
| | 0 | m/7500 | m/3750 | m/750 |

Dispersity and Form of Developed Silver

After this compilation of factors preventing reduction in photographic emulsions, one might be surprised that it does occur. *E'pur si muove*. The mere abrogation or penetration of barriers does not appear in itself sufficient, the rôle of silver and silver sulfide specks seems undeniable. How do these act, what actually takes place?

Much is shown, yet thereby new questions posed, by visible record of the development of silver halide grains. Not to the naked eye, of course, but to this cyclops armed with microscope, camera, cine-camera, and electron microscope. The eye functions best with green light 5600 Å. The practical limit of resolution (with

* With reference to the hypothesis of latent image formation of M. L. Huggins noted later.

ordinary light) is conditioned by the numerical aperture of the lens and the wavelength of the light. With N. A. = 1.41 and light of *ca.* 4200 to 4400 Å, this will mean 0.16 μ to 0.20 μ . Slightly superior results can be attained with ultraviolet light (and quartz optics), but the gain is hardly worth the effort. Under these circumstances, the depth of focus is of the same order as for resolution. This means that for sufficient exposure the "appearance" is a mere optical section complicated by shadows of the out-of-focus regions.⁴⁸ For photomicrography A. P. H. Trivelli has sought to overcome this by cumulative exposures, each an underexposure *per se*, at different focal distances or image depths, but this is a tedious procedure seldom used. The useful magnifications under these conditions lie from 1000 to 2500 diameters. None the less, with these humble means, much was accomplished. Observations by Hodgson⁴⁹ showed that development started at discrete points on the grain surface. The qualitative observation was extended and made quantitative by The Svedberg.⁵⁰ He and his coworkers showed that these "development centers" were distributed among and over the grains at random. Mathematically: if we suppose q development nuclei are scattered haphazardly over a number of grains of total surface S , then the probability that a grain of area a will get r development nuclei is

$$p_r = \frac{(aq)^r}{r!} e^{-\frac{aq}{S}}$$

it being assumed that a grain receiving one nucleus is developable. Then the probability of a grain receiving no nucleus, or remaining undevelopable is

$$p = 1 - e^{-\frac{aq}{S}}$$

wherefore the percentage number of developable grains of a certain class-size a is given by the expression

$$p = 100 (1 - e^{-ca})$$

where a is the class-size (projective area) and c is a constant. This expression in the logarithmic form

$$\log [100 - \log (100 - p)] = \text{constant}$$

has been compared with experiment^{50a} and verified.

From this evidence for discrete development centers arose a discussion as to whether they derived from a probability distribution of discrete light quanta⁵¹ or from preëxisting "sensitivity centers."⁵² The evidence in favor of the latter view was greatly strengthened by the discovery of the photographic sensitizing effect of silver sulfide specks.⁵³ The rôle of such nuclei in latent image formation and developability was shown to consist, not in increasing the actual photochemical yield of silver atoms, but in concentrating this silver about the speck,⁵⁴ a result incorporated in the "concentration speck" theory.

This theory proffered no explanation of the mechanism of concentration. In the "orientation" hypothesis, Sheppard⁵⁵ suggested that around a concentration speck was formed a "potential trough" to which electron-wavelets moved, and wherein photoelectrons combined with silver ions to form metallic silver. Intervention of a photoelectrolytic process, involving the migration of silver ions, was suggested by Sheppard,⁵⁶ and by Sheppard and Trivelli,⁵⁷ following the work of Tubandt and his associates on electrolytic conduction in silver halides. This view was developed more explicitly by Trivelli⁵⁸ in a photoelectrolytic hypothesis of

latent image formation. According to this, the essential sensitivity nucleus was a speck of silver sulfide *and* silver. Under the influence of light, this attracted silver ions which were discharged by photoelectrons, forming more metallic silver.

The suggestion of migration of silver ions was not at once followed up, and it was left to Gurney and Mott¹⁶ and to Webb⁵⁹ and to Berg⁶⁰ to properly evaluate its importance, in terms of the Gurney-Mott theory of latent image formation. Briefly, since we can only discuss the latent image as a prelude (but an essential one) to development, they supposed that electrons released by light from the "filled levels" of the crystal—atomistically the process $\text{Br}^- + h\nu \rightarrow \text{Br} + e^-$ —attained to upper "conductance levels" and then were "trapped" by silver sulfide or other sensitivity specks. The specks, becoming negatively charged by the electronic excess, attract silver ions which react to form silver atoms crystallizing on the speck. Again we cannot deal with the important experimental evidence⁵⁹ from reciprocity failure at high and low intensities of light, and at low temperatures, which is thought to support this hypothesis, but we have indicated already a corollary in regard to chemical development. We come now to further photomicrographs and electron micrographs of developing grains. It was observed by Scheffer⁶¹ in 1907 that initially developing grains frequently showed protuberances, evidently of reduced silver. He supposed that adjacent silver halide grains (which he termed "nutrient grains") went into solution, and that silver reduced by the developer was deposited at specific points on the grain which then grew outward. It may be pointed out that calling in adjacent grains was unnecessary; it would suffice for adjacent silver halide of the same grain to perform the task of nourishing the growing points, and, in fact, in some way or other this conception is necessitated by the progress of the grain to complete reduction.

Further high power photomicrography of the developing grain did not support this localized outward process as necessary and sufficient. Studies with weak and retarded development showed that the developed grain may be a slightly shrunken pseudomorph of the original silver bromide grain.¹⁸ A morphological survey of grain development with several developers, by Trivelli and Sheppard,⁶² showed that outward processes did indeed occur with all these developers, starting apparently from localized development centers. However, while these may be connected with deformation in development, this is not certain, and many grains developed to more or less definite pseudomorphs of the original bromide grain. Some of these results are reproduced in Figure 8.

It is necessary to mention here that x-ray diffraction studies have shown the developed image, even in early stages, to consist in the main of regularly crystallized silver having the normal cubic lattice.⁶³ Consideration of this, and of the apparently compact state of the developed grain might have suggested that a principal matter to be explained in development is the exodus of bromide ions—at least no less important than the reduction of silver ions. But, in fact, this was little considered, in resemblance to the neglect in so many theories of the latent image to consider the fate of the halogen. But this at least is small in amount, whereas in development, numerically for every silver ion reduced a halide ion must be evacuated into the solution.

A turn of great importance to the problem was given by the application of the electron microscope. The degree in which this instrument has improved the elucidation of fine structures is dealt with elsewhere in this volume.* Its first application to the developed image was made by M. von Ardenne¹⁸ and this has been much extended by Schoen and Hall.¹⁹ We shall leave till later its revelations as to "fine grain" and "physical" development. Its momentous disclosure for chemical development of silver bromide was to show that in early and intermediate stages the developed grain consists of a tangle of rather flat filaments, recoiling on themselves, sometimes thickening and eventually more or less coalescing (cf. Fig. 9). That

* See paper on the electron microscope by A. E. Prebus in this volume. Editor.

FIGURE 8. Morphological survey of development of silver bromide grains by *p*-aminophenol developer.

FIGURE 9. Electron micrographs of developing silver halide grains.

this quasi-linear progress of development is primary and fundamental is shown by the electron micrographs of a Lippmann emulsion before and after development (cf. Fig. 10). Each silver bromide grain—of the order of 0.2 to 0.4μ in diameter—is shown to give a single filament or hair. There is much to suggest from the electron micrographs of ordinary negative grains in various stages of development that this is the elementary or unit process in their case also, as shown by successive stages of development on one-grain layer preparations. However, certain electron micrographs obtained by Hall and Schoen with partially developed silver bromide crystals,

FIGURE 10. Electron micrographs of Lippmann emulsion, before and after development.

FIGURE 11. Electron micrograph of surface tangle of silver on developing silver halide grain.

fixed and washed on the object slide, suggest that quasi-filamentous growth may spread over the surface of the grain and throughout the crystal. This is illustrated in Figure 11. E. E. Jelley⁴⁸ has pointed out that "frequently, angular enlargements are seen in the filaments . . . , and many of these enlargements have an obviously triangular contour."

"This is a strong indication that the sides of the filament correspond to the octahedral (111) faces of the silver crystal, so that the filaments may be considered as silver crystals which have grown chiefly in one dimension." Before this consideration of the revelations of photomicrographic and even more of electromicrographic revelations of the development of *individual* grains of silver halide, we have dealt mainly with the *statistical* behavior of very large numbers of grains in development. We may regard the conclusions as to various "barrier" effects controlling the initiation of reduction in the grains as so far well founded. The optical and electron microscopes are not fitted to testify as to these conclusions. *Per contra*, these instruments give us the most definite evidence available as to the actual progress of reduction of a grain once the process is initiated. Reconciliation of the statistical with the individual data will give a definitive theory of development. At the point at which we have arrived, the question is by what mechanism is the filamentous growth of the developed grain to be explained?

Interfacial Conditions

Except for an extreme form of the Gurney-Mott hypothesis it is admitted that the process must commence and continue at the triple interface,

. . . provided, that is, that the original Ostwald, etc., and recent Reinders¹¹ theory of reaction of silver ions in solution is not accepted.

The principal objection to the former hypothesis is that it makes no satisfactory provision for the exodus of halide — $\overline{\text{X}}$ — ions into the solution. On the other hand, the older hypothesis by aqueous solution has too low a concentration of silver ions to offer to meet the demands of the reaction velocity.* Let us for the moment discard these two dualistic hypotheses, and consider only the advance of the *triple* interface—the metallic silver phase gaining at the expense of the silver halide phase by the energy of the oxidation of the developer by the silver ions. For the moment it is not of principal importance whether this occurs by way of the adsorption of reducer ions or molecules to the silver halide as suggested by Sheppard¹³ or to the silver metal, as proposed by Rabinowitsch.¹⁴ In both cases it is agreed that it is the triple interface which is the essential focus of the process. It is important that in either case continued contact of the developer solution with the solid phases is required. This is vital in regard to an aspect of the problem which has been much neglected in recent theorizing on reduction in the solid phase, *viz.*, the removal of the halide ions of the lattice. In the classical "solution" theory, this occurred so to say concurrently with the solution of the silver ions. The *order* of developability, $\text{AgCl} \approx \text{AgBr} > \text{AgI}$, observed, if not quantitatively at least qualitatively in both practice and experiment, follows of itself. However, for the newer hypotheses as to development in the solid phase, difficulties arise, since the mobility of halide ions in the solid lattices is admittedly very low, and requires very high "activation ener-

* Large grains—of 2 to 3μ —may be completely developed within a minute or two!

gies" compared with the silver ion. We may conclude provisionally that *the hydration and diffusion away of the halide ion is a dominant factor in the process of chemical development.* A condition for this is the continuous presence of the aqueous developer at the site of the elemental chemical reaction.

However, if we admit pure "adlineation" of developer ions at the triple interface, with resultant reduction of silver ions to silver atoms which "crystallize" on the speck, we do not obtain immediately a condition for filamentous processes. About a symmetrically circular speck of silver sulfide or silver in octahedral (111) surfaces of a silver halide crystal this should give a regularly increasing circular area of reduced silver. Rabinowitsch¹⁴ has described such a phenomenon, observed with a single nucleus produced on special large silver bromide crystals—6 μ and greater—prepared according to a procedure of Meidinger.⁶³ The area is said to have increased according to the square of the time, in accordance with an autocatalytic reaction in two dimensions. However, this process is stated to have occurred within the "induction period"—which phrase is not defined—and it is further stated that with "fast" developers, a "stormy" process sets in with the formation of protuberances or "explosions" shot out from the grain.

The phase of superficial spread may occur and is in accord with observations of the formation of faint superficial films of reduced silver in the earliest stages of actual development,⁶² when presumably several such zones from more than one nucleus might meet. However, it is evident that it does not help to account for filament formation. A. J. Rabinowitsch has suggested rather vaguely that the "stormy" period of development is occasioned by the necessity of formation of a new crystal lattice of metallic silver with different parameters—*e.g.*, $d\text{AgAg} = 4.08 \text{ \AA}$ compared with $d\text{Ag}^+\text{Ag}^+ = 5.78 \text{ \AA}$ in silver bromide.

If the reaction takes place in the crystal, or at least in the silver halide crystal contiguous both with developer and metallic silver, this appeal to the principle of minimum work is important. It would have no bearing here if the silver ions were reduced from aqueous solution. Bernal⁶⁴ has pointed out certain pertinent applications of the principle of minimum work in connection with transformations in the solid phase. As he says "It is fairly obvious that any change inside a solid cannot involve the movement of any of its parts outside the range of the interatomic forces of its neighbors. Consequently, one of the main consequences of solid reactions must be a tendency to keep to the original configuration. Changes which leave this only slightly changed will occur very much more readily than those which require serious alteration." In general conformity with this, and somewhat contrary to the specific reference of A. J. Rabinowitsch, Dankov⁶⁵ has discussed both the formation of the latent image and its development. He postulates "the process

should go on in that most simple direction which ensures a minimum change of the orientation of the silver atoms (ions)." This involves "minimum translocation of the atoms during the process." He goes on to show that *silver bromide* exhibits particular advantages in this respect. In Figure 12 it is evident that the lattice of silver bromide can transform itself into the silver lattice with hardly any change in the spatial disposition of the silver atoms. Also "the complex of cube planes (100) in the $[\text{Ag}^+\text{Br}^-]$ lattice will correspond to the octahedron (110) and cube (001) planes in the $[\text{Ag}]$ lattice. At the same time, according to the principle of dimensional conformity,* the distances between the silver atoms in the cube planes (001), which retain their denomination even after the silver bromide has turned into the metal do not change at all after bromine [in the case of print-out and latent image forma-

* This is the form in which Dankov states the principle of minimum work.

tion, but of bromide ion in the case of development—interpolation by the writer] has been removed from the crystalline lattice.” Simple calculation is in agreement. The diagonal of the cube plane for silver $a = 4.077 \text{ \AA}$ equals $\sqrt{2}(4.077)^2 = 5.75 \text{ \AA}$, which approaches closely to the constant of the silver bromide lattice, *viz.*, $a = 5.76 \text{ \AA}$.

There is less conformity in the case of silver chloride, where the diagonal of the cubic plane in the silver nucleus (5.76 \AA) is 3.8 per cent greater than the edge of the cubic nucleus of silver chloride (5.54 \AA). However, Dankov's supposition that

FIGURE 12.

this may account for a more restricted photographic utilization of silver chloride is unwarranted. The defects of silver chloride relative to the bromide are in the matters of spectral sensitivity, and of greater solubility and reducibility. So far as the postulate of minimum work is effective, the fact that silver chloride, *ceteris paribus*, develops at an equal or greater rate than silver bromide shows that some compensating factor or factors must intervene. This factor we consider to be the easier removal of the halide ion. All the recent hypotheses on chemical development, which predicate reaction in the solid state, have concentrated on the question of reduction of the silver ion, with little attention to the equally important matter of the removal of the halide ion. Where some attention has been paid to this, it has been by way of rather *ad hoc* suppositions, most of which involved larger motions

of the halide ions in the lattice than are consistent with the data on the conductance of the ions in the solid silver halides. These, as is well known, indicate that movement in an electric field is practically confined to the silver ion.

Thermal Energy Balance

To obtain a value for the "heat of development" the simplest procedure is to regard the process as composed of two steps, *viz.* (a) solution (b) reduction of hydrated silver ion to metallic silver. Whatever the mechanism, the products are metallic silver and halide anion. The unknown quantity is then the heat of reduction of the silver ion.

For three silver halides we have for (a)—heat of solution:

| | |
|------|----------|
| AgCl | 15 k cal |
| AgBr | 20 k cal |
| AgI | 27 k cal |

For (b) values have been obtained from the reaction

Approximate calculation of the heats involved gave about 92 k cal/mole. This figure is likely to be somewhat high because certain specific heat effects were neglected. On the other hand, imperfectly corrected experimental determinations gave 72 k cal/mole. This is probably low, owing to disregarded heat losses, evaporation, etc. Pending values for other developers, it appears that for silver bromide, with a "heat of solution" of 20 k cal, there should be a net heat balance of some 50 k cal available per mole AgBr on reduction by hydroxylamine. A supposedly more energetic developer, as hydroquinone, should afford more heat on reaction. The calculated value, for one equivalent of silver ion was found to be 20 k cal and experimentally 28 k cal. Again subtracting the heat of solution of silver bromide, we have a favorable balance possible of *ca* 8 k cal.

These are larger amounts than postulated by Weissberger;²³ it remains to consider how they compare with "activation energies" likely to be important in the crystal.

The "activation energies" in question would be in the first place those for mobilization of the silver *and* halide ions—at any rate from the point of view of processes in the solid. The maximum possible values for these would be those deducible from the theory of the electrostatic potential energies in the lattice⁶⁶ uncorrected for polarization and other factors. These are for cubic (B1) type silver bromide:—

Silver ion 13.2×10^{-12} erg per atom or 200 k cal/mole

Bromide ion 42×10^{-11} " " " " 640 " "

These "limiting values" are all undoubtedly very much too high, because no account is taken of polarization and other factors. Experimentally, estimates of the activation energy, assumedly for the silver ion, are obtainable from the electrolytic conductance. If we assume⁶⁷ that the activation energy for the S. I. region:—

$$E = 1/2 W + U$$

where W = activation energy for movement of Ag^+ ion from a stable lattice position to an interstitial position,

U = activation energy for an interstitial silver ion,

then $W = 2(E - U)$,

and we have to have some measure of U to estimate W . It has been suggested that the activation energy for S. S. regions may be taken for this. We give in Table IV, some estimates for the work function or activation energy (supposed for the silver ion) for three halides. All values are in k cal/mole.

Table 4

| Substance | U | E | (a) | W (b) | (c) |
|-----------|-------|----|-----|----------|--------|
| AgCl | 8.0 | 20 | 25 | 22 | 24 |
| AgBr | 7.5 | 15 | 20 | 20 | 15 |
| AgI | (5) * | 10 | — | 19 | (10) * |

(a) E. Koch and C. Wagner, *Zeit. phys. Chem.*, B 38, 295 (1937).

(b) H. Reinhold, *Z. Elektrochem.*, 39, 580 (1933).

(c) Unpublished data of Sheppard, Vanselow and Happ.

* This value is based on the assumption $U = 1/2 E$.

Supposing that these values are more nearly correct than the "limiting values" obtained from the electrostatic potential, then the net energy balance of the reaction of developer with silver halide might well be enough in principle to support Weissberger's hypothesis. In fact, considerably more heat is then available than his tentative estimate provided. The "hot spot" hypothesis becomes more plausible, but there still remains the recalcitrant fact that the rates of development of the silver halides are *not* in the order apparently demanded by conditions for mobilization of the silver ions in the solid phase.

Another possible phase of the action which would be favored by rise of temperature is solution of silver halide in halide ion solution—locally provided by escaping halide. This will be considered in dealing with "fine grain" development.

These purely thermochemical considerations only indicate the maximum work possible in a process and not the true thermodynamic limiting conditions. However, the probability of a large net surplus of energy available for "activation" is roughly indicated by them, and, therefore, of localized or "hot spot" effects. Colloid chemistry has been defined by Bancroft as the chemistry of interfaces, of bubbles and filaments.⁶⁸ The colloid chemist knows of conditions where a reaction becomes evidently periodic in space, *e.g.*, in Liesegang ring formation. There are also examples of reactions becoming quasi-periodic or pulsating in time, such as the decomposition of hydrogen peroxide at a mercury surface observed by Bredig. In this case there is a periodic making and breaking of an oxide film, a transient "bubble." There are, moreover, other instances of filament formation in physical and chemical processes. Many substances crystallizing out in a colloid, such as a nitrocellulose film, do so, by the constraint of a rigid foreign medium, in plumes of spirally curved filaments or trichites.⁶⁹ * However, in such cases the whole medium is supersaturated with the material of the crystals. Much more similar to the present case is the "growth" of alumina filaments from pure aluminum specked with a mercuric salt.⁷⁰ † This is particularly interesting, because it is an oxidation-corrosion, whereas development is a reduction-corrosion. Also, it has been observed that mercury globules in an atmosphere of iodine vapor appear to eject filaments of mercuric iodide.⁷¹ It is notable that in the great number of topochemical reactions, in a solid phase, as they were termed by Kohlschütter⁷² there is but little mention of filamentation, the formation of "hair silver" by the reduction of silver sulfide by hydrogen at rather high temperatures (400°-500° C.) being the most noteworthy. It is possible that electron microscope studies of many of these, *c.g.*, the thermal decomposition of silver and mercurous oxalates, of silver and other azides, might reveal new examples.

The production of dendritic growths in electrolysis is well known, as also that of "inorganic vegetation" in the growth of precipitates in silicate solutions. Speaking broadly, these are all instances of a general principle. They tend to occur when the "ordering" of a new solid phase (in its state of minimum potential energy) is unable to keep pace with the rate of condensation (precipitation)⁶⁹ and particularly

* Various papers in earlier volumes of this series discuss the effects of colloids on crystallization. See also paper by W. G. France in this volume. Editor.

† See paper on "grown" alumina by H. Wislicenus in Vol I of this series. Editor.

in the presence of a mechanically resisting medium.* Examples of this in the recrystallization of silver bromide in gelatino-silver bromide layers have been given by Trivelli and Sheppard.⁶⁹

It is likely that such a peculiar somatic modification as filament production in the chemical development of silver bromide—or rather, of silver iodo-bromide crystals—is the resultant of several conspiring factors. If we are not satisfied with the simple dualistic hypothesis of Gurney and Mott (*cf. inf.*) mainly because it makes no provision for the exodus of halide ions from the solid crystal, but also because it requires that the reducer adsorb to metallic silver specks, and donate electrons, without considering that an oxidation product, *e.g.*, quinone, will equally attach itself and accept electrons from a silver speck,† we seem forced to look for some other operative process in the solid silver halide. Moreover, it would seem that such a process should have the possibility of a *pulsating* character in time, and, probably of a mechanically disintegrating character on the crystal. Such a process may be derived perhaps from a new theory of latent image formation and its chemical development due to M. L. Huggins.⁷³ The writer has had the privilege of a preview of Dr. Huggins' presentation of his theory. No more than the writer is in entire agreement with the conclusions which Dr. Huggins draws as to the latent image and its development, no more will the latter be as to certain consequences deduced here. The foundation which Dr. Huggins presents we consider to be very truly laid and of great importance. Briefly, he shows that in solid silver bromide, which is found to crystallize predominantly in the B1 (NaCl, cubic) type, there exists the possibility of easy transition, under given conditions, to a B3~B4 (ZnS) type. This structure is shown to be only slightly higher in energy—*i.e.*, lower in stability—*per se* than the B1 type, with which it is *tautomeric*, to speak in the language of organic chemistry. The argument for this must be considered in Huggins' own papers; we shall consider only certain aspects and consequences. It should be said at first that a greater tendency for silver bromide to adopt this structure than for silver chloride is consistent with the conclusion that the former shows a greater degree of covalent bonding or of homopolar valency, than the latter.⁷⁴ The writer has indicated elsewhere the possible importance in the photographic process with silver halides of the transition from the ionic (electrostatic) to this other type of bonding. Huggins points out that the probability of a transition B1→B3~B4 would be increased by the presence of a small percentage of iodide, such as is usually introduced into gelatino-silver bromide emulsions.‡ A very important property of the B3~B4 structure brought out by Huggins is this. It contains "holes" of positive potential and "holes" of negative potential (*cf.* Fig. 13). He points out that "the former are possible sites for extra electrons, *e.g.*, photoelectrons—an electron in such a site stabilizes the structure by at least 1.10^{-12} erg or 0.6 e v." The presence of extra electrons favors the transition from a B1 to a B4~B3 structure. Huggins suggests that "the latent image consists of a small region of the crystal or crystal surface in which the atomic arrangement is—the B3, or cubic ZnS type—stabilized by the presence of extra electrons (photoelectrons)." In this writer's view, which on this point is not to be regarded as identical with that of Dr. Huggins—this region might be regarded as an aureole surrounding or adjacent to a sensitivity speck of silver sulfide, or its equivalent of other "noble" sulfide or metal. In the "orientation hypothesis" of the concentration speck the writer has suggested⁵⁵ that the speck is surrounded by a potential trough tending to attract electron-wavelets from any part of the crystal absorbing light. The Gurney-Mott hypothesis proposed that the photoelectrons migrated to the speck itself,

* One wonders what form H. G. Wells' time traveller and his machine might have taken if he had "precipitated" in some ancient volcanic upthrust long forgotten, or in the Tower of London. (*Cf.* H. G. Wells, "The Time Machine.")

† Electronically the condition of a silver electrode in a redox medium.

‡ From 1 to 5 per cent.

giving it an excess negative charge which attracted interstitial silver ions. Huggins' suggestion appears to embody important features of both these hypotheses, and to be superior to either.*

Let us return, prior to the latent image, to the formation of a sensitizing speck, *e.g.*, of silver sulfide, in a silver halide crystal. This is produced by the breakdown of

FIGURE 13. Extra charge capacity of Huggins' B3 structure for silver bromide.

an antecedent organo-silver halide complex⁵³ with elimination of halide ions and of organic radicles. It occupies, therefore, less volume than the earlier complex, and indeed than the silver halide which it replaces. In these relatively violent transformations it is reasonable to suppose that contiguous silver bromide would pass from the B1 to the B3—B4 structure—of somewhat higher energy, and specifically in the less stable structure, having a volume about 13 per cent greater than that of an equivalent

FIGURE 14. Continuity of B1 and B3 lattices of silver bromide.

amount of B1. The intercalation of such a region with neighboring B1 is fully described by Huggins; in particular, it may be noted that the bromide ion distribution would be continuous throughout the whole, "only the distribution of silver ions and extra electrons being different in the two parts." (cf. Fig. 14). This zone or aureole of B3 structure adherent to a speck is the destined trap for photoelectrons on ir-

* An important aspect of the "orientation hypothesis" was that it allowed for more than a chance accretion of photolytic reaction product around the speck. What it did not provide *per se*, which the G.—M. hypothesis did, was an attraction center for silver ions.

radiation of the grain. Thereby the dimensions of the structure would tend to contract to those of the adjacent B1 structure. We may suppose, however, that it is at least equally possible for the electrons to spread back into adjacent B1, producing more B3, a possible factor in the phenomenon of "growth of the latent image."⁷⁵ In any case, a more or less stationary state can be assumed to form about the speck for a given and relatively slight illumination; we are not interested at present in considering the progression under further irradiation to a "print out" image. Huggins has pointed out that the extension of the B3 structure may well be greater in the surface of the crystal than in the interior. In general, as he shows, "the boundary between the two structures (B1 and B3) . . . could shift very readily, one atom at a time. A silver ion on the B1 side . . . may shift only slightly . . . in order to take its place as a portion of the B3 part of the crystal. This shift would require only a very small activation energy—in the neighborhood of 10^{-12} erg or 14.6 k. cal." It is important to realize that a suitable net plane of such silver ions retaining sufficient electrons is already equivalent to a (111) plane of a silver metal crystal. In explanation of filament formation, we are inclined to insist upon the tautomerism of the structures:

where B3' is the B3 structure of greater volume, *i.e.*, less extra electrons. This B3' structure may be that which adsorbs the developer, receiving electrons; partly, as extruding into the developer (losing bromide ions), and collapsing to a silver lattice, partly handing on electrons to form more $B3 \rightarrow B3'$ from B1. The rôle of a sensitivity speck of silver sulfide, soon reinforced by metallic silver, is to centralize this sequence of events and permit its continuance. It has been forgotten that a silver or silver sulfide speck can only receive electrons in so far as these are in defect, that it will, in general, at least equally attract an oxidant, *e.g.*, quinone, as—where electronically defective—a reductant. Provided reduction takes place in a B3' zone, somewhat extruded—in virtue of its greater volume—from the surface of the crystal but adherent to the therewith growing silver, there seems no inherent difficulty in protrusion of filaments—initially at any rate. The bromide ions are thereby brought to the surface, to undergo hydration, and escape.

Within the crystal we may suppose that the variable expansion and contraction induced by the pulsation of $B3 \rightleftharpoons B3'$ formation proceeds faster than any large movements of Ag^+ ions, let alone of bromide ions. A splitting of the crystal grain, admitting developer, and renewed filament formation, will ensue, the process having some resemblance to the "branching chain reactions" discussed by Semenov⁷⁶ and instanced by W. E. Garner⁷⁷ in reference to the purely thermal decomposition of solids. It must be remembered that the silver halide grain is enclosed in a mechanically resisting integument of gelatin, which may allow at the start some penetration by filaments, but not to an unlimited amount. In many cases, oxidation products of the reaction will tan this integument, increasing the resistance. It is to this factor possibly that we owe the relative conservation of figure of developed grains.⁴⁸ But, in reverse, we must either admit inward filament formation—which requires considerable bromide ion mobility in the solid crystal, or such a splitting as we have indicated. We cannot pretend that the mechanism of filament formation in the chemical development of gelatino-silver (iodo) bromide grains is yet fully elucidated. We do consider, however, that the theory of M. L. Huggins is likely to give the most satisfactory explanation. The reversible change of volume which it allows, according to surges of electron acceptance and donation, requires only small displacements of silver ions, of low activation energy. At the same time, this expansion and contraction affords the occasion for bromide ions to hydrate and escape. Flux and re-

flux of electrons could be assisted by the silver sulfide-silver speck acting as an electrode in a redox medium—this, however, being only of secondary moment.

Before leaving this aspect, it is necessary to consider the cases of silver chloride and silver iodide. The prospects for the $B1 \rightarrow B3 \sim B4$ transformation with the former appear considerably less promising than for silver bromide. The electric conductance of AgCl in the S. I. region is considerably less than for AgBr, and the activation energy is higher. However, it seems to exist at temperatures below 200° C. chiefly in the S. S. state, having a much higher conductance—*i.e.*, mobility of silver ions, and lower activation energy, conditions assuredly favoring the possibility of a $B1 \rightarrow B3 \sim B4$ tautomerism. Over and above this, however, we must consider that reduction from aqueous solution may play a considerable part with silver chloride. Its solubility in water is some hundred times as great as for silver bromide, and the tendency to covalent binding much less. The energy of hydration of the chloride ion is also greater, and these factors probably account for the more ready reducibility and developability of silver chloride.

The case of silver iodide is quite different. This crystallizes, at ordinary temperatures, in either of the two closely related "tetrahedral" structure, B3 (cubic) and B4 (hexagonal) in each of which each ion is surrounded tetrahedrally by four of the other kind. Huggins suggests that "the preference of the iodide for the tetrahedral structures may be explained as due to the greater tendency of iodine (than of bromine) to form covalent bonds with silver. Electron pair bonds between all adjacent atoms are possible in the B3 and B4 structures, but not in the B1 structure." With this preëxisting B3~B4 structure, it might be thought, according to the previous argument, that silver iodide should be even more readily chemically developable than silver bromide, whereas the case is quite the contrary. Pending a further investigation by Huggins of the energetic conditions for redistribution of electrons and ions in silver iodide, we would suggest the following aspect of the stability of silver iodide. It may be considered that the iodine atom-ions of the structure resonate between these configurations:—covalently bonded iodine atom, electrostatic iodide ion, and one-electron bonded iodine with the other electron in a "hole" of positive potential. This is in agreement with the behavior of silver iodide in regard to light (photolysis) and in regard to reduction by developers. There would be less incentive to the formation and reception of foreign electrons, and to any change of lattice dimensions. Whatever the fate of Huggins' theory, it is a tantalizing thought that there are questions which only the colloid chemist can put, and which only the crystallographer can answer.

Physical and Fine Grain Developments

The relatively early differentiation between "physical" development and "chemical" development had in it somewhat of the same logical, *i.e.*, verbal contrast, as that between the physical and the metaphysical, the latter being what was beyond or outside the physical. It may be remembered that physics was already an embryonic science when chemistry was still mostly a mystery, that is, alchemy. With the advent of physical chemistry, it was assumed that (*cf.* p. 475) the processes were essentially the same, the silver halide going into aqueous solution to be reduced. Then later, with chemical physics arising, the differentiation became reasserted, with increasing insistence that in "chemical" development the actual reduction of silver ions to silver and their aggregation to metallic silver took place within the solid phase, the silver halide crystal. We have discussed some of the possibilities and some of the difficulties of this conception. The "adsorption theory" of development seemed to offer a sort of middle way out of the difficulties by making the interface between the reducing solution and the solid silver halide grain the actual locus of the reaction—or rather the triple interface, silver halide: silver metal: developer. As we have seen, this conception does not explain too readily the revelations of the electron microscope.

and filament formation.* There has been a tacit assumption that "physical" development is so well understood that it would suffice for "chemical" development to be referred to that category to regard it as thereby "explained." But how, if "physical" development has its own problems? They certainly exist, photographically speaking, and perhaps, in some cases at least, chemically.

We shall return to the photographic aspect, meanwhile, let us consider again the simple matter of "physical" development by ferrous salts.

There is generally very rapid—so-called instantaneous—reaction, between "ions" in aqueous solution. But this is not always the case.⁷⁸ Thus the reaction between ferrous ions and silver ions in aqueous solution shows a definite induction. This was attributed by Roberts and Soper⁷⁹ to the time required for supersaturation with silver atoms. There are other possible causes of induction. In this case the reaction $(\text{Fe}^{++})_{\text{aq}} + (\text{Ag}^+)_{\text{aq}} \rightarrow (\text{Fe}^{+++})_{\text{aq}} + [\text{Ag}]_{\text{met}}$ is saddled with a very considerable potential barrier. This is caused by the similarity of the sign of the charge, and the hydration of the ions. The free energy of hydration of the silver ion, 95.5 *k cal*s, is very considerable, while that of the ferrous ion is probably of the order of 400 *k cal*s. In both cases the water molecules of their hydrospheres will be strongly polarized and similarly oriented. There is a condition similar to that indicated by James as causing an induction period in chemical development. The problem for the ions is how are they going to get close enough together for the ferrous ion to hand over an electron to the silver ion. We disagree with Roberts and Soper's view that this phase of the reaction is *de jure* and *de facto* "instantaneous." We have always considered that the structure of ionic aqueous solutions is fundamentally micellar, due to the electrostriction of water molecules about the ions,⁸⁰ and this has been quantitatively reaffirmed in modern theories of the hydration of ions.⁸¹ With this in mind, a tentative sketch of the process can be outlined which may indicate that it is not so unlike the process considered in "chemical" development.

The ferrous ion is not *per se* very stable, it interacts readily with hydroxyl ions to form hydrous ferrous oxide. This hydrolysis is repressed by increase of hydrogen ion, but the catalysis of silver ion reduction can hardly be due to this alone. Ferrous ions will tend to form ion-pairs, and we suggest that in the present case this involves the formation of a one-electron bonded dimer: $-(\text{Fe}^{++})_{\text{aq}} + (\text{Fe}^{++})_{\text{aq}} \rightarrow (\text{Fe}^{++} \cdot \text{Fe}^{+++})_{\text{aq}}$ which would be stabilized by charge resonance between the cores. A hydrogen ion, H_3O^+ , consisting of a proton *inside* a water molecule, can penetrate readily enough the hydrosphere about the ferrous ion pair, and stabilize the complex against hydrolysis. Between the hydrosphere of such a ferrous ion complex and that of a silver ion or of a silver ion pair, there will exist chains of water molecules polymerized by hydrogen bridge formation. The initial stage of reaction or reduction we conceive to be effected as follows: A proton of the hydrion in the ferrous complex is neutralized by the lone electron of the latter, but receives a positive charge from the nearest bridge hydrogen connecting with a silver ion. By this type of "tunnel" at the other end of the chain a hydrogen atom in the silver ion pair hydrosphere takes a positive charge from a silver ion of an ion pair. There is formed another one-electron bond pair $\text{Ag}^+ \cdot \text{Ag}^+$, which we may regard as a metallic silver atom adsorbed to a silver ion, or conversely. The "tunnel" process producing these may be regarded indifferently as a movement of an electron along the chain from the $(\text{Fe}^{++} \cdot \text{Fe}^{+++})_{\text{aq}}$ complex

H⁺

to the silver ion pair, or as a movement of positive charges (positrons) from the silver ion pair to the ferrous complex; evidently it comes to the same thing, and this

* One is reminded of the conflict between the uniformitarian and the catastrophic schools of geologists in the 19th century. For the former, relatively slow and regular deposition of strata by sedimentation from aqueous suspension was all prevailing, for the latter volcanism, the upthrust and solidification of molten magma. There seems to have been room for both the isothermal and the adiabatic processes!

process we regard as constituting the primary phase of the "induction period."

The secondary phase may well consist in the coalescence of such silver ion-atom pairs to form binary and ternary nuclei of a metallic silver lattice³ with an accompanying reduction of the hydrosphere barrier. There would even be possible a replacement or hydrogen bridges by silver ion-atom chains:— $\text{Ag}^+ \cdot \text{Ag}^+ \cdot \text{Ag}^+ \cdot \text{Ag}^+$. . . with complete continuity between the reaction in the induction period and that in the "metallic silver" catalyzed reaction. In this stage, the hydrospheres of the ferrous ion complexes are dissipated, and ferrous, ferric and argentous ions finally establish equilibria on silver crystals. It is not necessary to suppose that the ions become naked gaseous ions at the surface of the crystal—though this must occur for silver ions incorporating in the lattice. It is sufficient that the hydrospheres become so thin that the probability of the transition discussed above becomes enormously increased, because the probability of such transitions is approximately inversely as the thickness of the barrier, and therewith the velocity of the reaction. If the structure of a liquid, of a solution, were so to say, static, instead of being only an averaged kinetic structure, generally isotropic because of the thermal energy, the chain mechanism might well give rise to filamentous forms of silver. This is disrupted because of the thermal energy, but when, as in electrolysis, a macroscopic anisotropy is applied to the solution, dendritic growths readily appear—so-called silver and lead "trees."

In the case of "physical" development with acid ferrous salt and silver nitrate solution, the "induction period" is abbreviated by the latent image. However, with this, and in all cases of "prefixation physical development" it is characteristic that a considerably lower "speed" or "threshold density" is manifested than that with chemical development. Partly this is because the "grain" of the reduced silver masses is finer, more compact, hence the covering power and optical density are lower. But partly also because, owing to the nature of a reduction-oxidation equilibrium, there is a high probability of the smallest nuclei being "oxidized" rather than silver ions being "reduced" upon them. This would be equally true if the "threshold" latent image nuclei consist of B3-trapped electrons as supposed by Huggins.* Correlatively, certain alkaline physical developers, to be noted shortly, give considerably higher threshold speeds than the acid ones.

Induction periods are manifest also in the reduction of silver ions by hydroxylamine and by hydroquinone. The kinetics of these reactions have been investigated by T. H. James⁸² to whose studies we refer in respect of characteristic details. Broadly, however, it may be said that they exhibit induction periods, catalysis by colloidal gold, silver sulfide, colloidal silver, and therefore autocatalysis. Foreign catalytic nuclei are overlaid and replaced by silver. It is an obvious necessity for "physical" development that there be an induction period and catalysis by the latent image and by the added metallic silver. Otherwise, that topographic distribution which constitutes a photographic image would not be conserved. The reverse of this does not appear to hold. Not every silver reduction showing an induction period is effective for physical development. Again with hydroxylamine, we consider that the fundamental reason for the induction period is the low velocity of the uncatalyzed homogeneous reaction, and that this is an expression of the low transition probability for electron exchange between donor and acceptor particles. According to the pH, hydroxylamine can exist in the following forms:—

The equilibrium is such that even at very high pH values the NH_2O^- ion can be present only in very low concentration. Also it should be noted that, unlike the

* Photographically, the essence of a latent image is topographic. Disappearance at one point, though balanced at another, is effectively destruction or loss.

nitrate and nitrite ions, it cannot be stabilized by resonance, which would accord with relatively low activity as a developer.⁸³ The ammonia-like neutral molecule should have a considerable dipole moment and probably a considerable energy of hydration. It would, therefore, have a large hydration sphere, reducing the probability of encounter with Ag^{\dagger} ions. Such encounters would occur, however, and, as in the case of ammonia, involve coördination between the silver ion and the hydroxylamine. Rearrangement in the coördination complex $\text{Ag}^{\dagger}(\text{NH}_2\text{OH})$ could lead to reduction of the silver ion and the adsorption to this of a silver ion, forming $\text{Ag}^+ \cdot \text{Ag}^+$, which we have suggested as the protonucleus for formation of metallic silver. In the catalyzed reaction, both silver ions and hydroxylamine molecules would be readily adsorbed to metallic silver as suggested by James with great increase of the transition probability.

The reduction of silver ions in aqueous solution by hydroquinone over a pH range of 5.15 to 6.27 has been investigated also by T. H. James.⁴⁰ The reaction shows a very pronounced induction period. This is diminished, and the reaction catalyzed, not only by colloidal silver, gold, palladium and silver sulfide, but to a considerable extent by quinone. While the action of colloidal silver and the other nuclei might be interpreted, as by Roberts and Soper in the case of ferrous ions, as discharging supersaturation with metallic silver, this can hardly be assumed for quinone—and hence is an unwarranted assumption for the primary homogeneous reaction in any case. With increasing pH there will be a change in the hydroquinone molecule in the sense shown below:

At pH 5 to 6 the concentration of the monohydroquinonate ion will be very small, still less that of the dihydroquinonate ion. The latter will have no great probability of reacting with free silver ions, because of the inequality of charge number.⁷⁸ While James' results indicate that the heterogeneously catalyzed reaction is chiefly carried on by the monohydroquinonate ion, and only slightly at the lowest pH values by the neutral molecule, it is possibly this latter which is chiefly active in the homogeneous reaction. However, considerable catalysis of this is effected by quinone, and James regards this as due to the formation of a very active semiquinonate ion by interaction of the dihydroquinonate ion with quinone.

The kinetics of the silver catalyzed reaction (which shortly replaces catalysis by gold, etc.) are best accounted for, according to James, by adsorption of silver ions to the metallic nuclei followed by their reduction *in situ* chiefly by the monohydroquinonate ion—the velocity of the catalyzed reaction being such that on correction for the rate of reaction between unionized hydroquinone and silver ions, a plot of the logarithm of the resultant rate against pH gives a straight line of slope 1.0.

There is a type of "physical" development which approaches "fine grain" development of negative emulsions, as well as the normal development of chloride and chlorobromide positive emulsions.* This is the reduction in alkaline solution of complex silver ions. The reduction of unprotected silver ions by alkaline organic de-

* As used for photographic papers and transparencies.

velopers is too rapid, the deposition of silver too immediate, to be photographically useful. Incidentally, this argues strongly against the view that induction periods are basically determined by silver supersaturation. It is the transition probability in the reaction between reducer and silver ion which is decisive. In the present case, where the activity of the reducer is very high, that of the silver ion must be greatly diminished to allow photographically useful induction. A photographically useful reaction is one in which the number of effective nuclei for the catalyzed reaction is substantially determined by the light exposure, no new nuclei being afforded by the reduction proper. Control of the silver ion activity in solution may be effected by formation of complex silver ions, as for example, silver sulfite

As concentration increases, there are perhaps complexes of higher order formed, as happens with silver ions and thiosulfate

Complex formation with the halides increases from the chloride to the bromide to the iodide. With the chloride the solubility data (of AgCl in KCl aq) permit interpretation in terms of

but with the bromide and the iodide this is no longer possible, and it appears that one must admit "solvation" by bromide or iodide essentially similar to the solvation of ions by water. But whether by coördination or solvation, the silver ion is increasingly protected from interaction with reducing ions or molecules. Not only is there induction, but the silver catalyzed reaction is also slowed down.

We have just considered reduction—and alkaline "physical" development—where the silver ions were introduced *ab extra*—as a prepared solution. But the solubility of the silver halides in solution of such coördinating and solvating ions is such that their presence in sufficient quantity in an alkaline (organic) developer must be considered to convert the process in part or wholly from "chemical" to "physical" development, the silver in (complex) solution being derived from the silver halide grains themselves. The principal silver halide solvent present in such developers is sodium sulfite*—though in early pyrogallol developers the alkali—ammonia—was such a solvent—and it is interesting to consider a few figures, for 25° C:—

Table V

| Concentration Na ₂ SO ₃ /liter | | Solubility of AgBr/liter | Solubility AgCl, liter |
|---|-------|-----------------------------|---------------------------|
| Grams | Moles | Grams | Grams |
| 25 | 0.20 | 0.44 | — |
| 50 | .40 | .90 | (2.1) |
| 100 | .80 | 1.90 | 4.4 |
| 125 | 1.00 | (2.45) | — |
| 200 | 1.60 | — | 9.5 |

It is evident that even within normal limits for organic developers (25 — 50 g./liter) the actual solubility is quite considerable. While this may not, for high alkalinity and activity, cause much direct participation, by reduction in aqueous solution, it may affect the process considerably by *etching* the surface of the crystal, and increasing surface irregularities.

* Unpublished data by A. Ballard and H. Yutzy of the Eastman Kodak Research Laboratories.

These effects become greater with increased concentration of sulfite, and decreased alkalinity and activity of the developer. On the other hand, the solubility in sulfite is decreased by increased concentration of soluble bromide. With the introduction and progress of the miniature camera, operating with 35 mm film the problem of "fine grain"—already glowing because of motion pictures—became incandescent. These midget negatives, not much larger than a postage stamp, must afford positive enlargements of say $2\frac{1}{4}$ by $3\frac{1}{4}$ inches upward. The *dispersity* of the developed silver was the controlling factor. Photographically, this dispersity falls into two levels, the basic level of individual, microscopic grain size, and a superimposed level of "graininess," which is an optical inhomogeneity visible at low magnifications, *e.g.*, 10 to 20 times. This "graininess" is a composite thing, partly due to the fact that there is a limit to the uniformity of "mixed uppedness" of a granular suspension, even of equi-sized grains, partly to optical superpositions in depth of any such clumped or non-uniform distributions, partly to actual infection of non-exposed by developing exposed grains.⁸⁴ The skill and art of the emulsion maker are employed to securing the best compromise in a given case of grain and graininess of the silver halide consistent with the specific requirements as to sensitivity and gradation. But it was found that something—though not everything—could be done by modification of the developer. The ultimate grain of the developed silver can be confined to the dimensions of the original silver halide particle, or even diminished, and the tendency to secondary clumping in development decreased.

Such results may be attained in various ways:

1. Increase in solvent power of the developer and reduction of its alkalinity and activity. The former may be obtained by increasing the sulfite concentration, *e.g.*, to 100 gms per liter, or by using *p*-phenylene-diamine, which is not only a reducer, but a fairly powerful solvent of silver bromide. Thiocyanate has been used also. Reduction of the activity of the reducer is effected chiefly by reducing the concentration of alkali and/or substituting a milder alkali such as borax. With such developers, increased time of development is necessary, in order that the same contrast (gamma) may be secured as with a normal developer. Comparing both developers *without* bromide* in the formulas, some loss of speed or sensitivity will be generally found with the "fine grain" developer. This is generally true, that the more the developer is modified in the direction of fineness of grain, the greater will be the loss of speed; to be compensated by increase of exposure.

2. The other procedure, which has not gained much application in practice, consists in a form of prefixation "physical" development, using an accessory silver solution and alkaline physical developer. A more direct idea of the dispersity of the developed image is obtained from photo- and electron micrographs of the grains in reduction of silver ions in solution.⁴⁸ Figures 15a, 15b and 15c show so-called "gray" silver produced by R. Liesegang and Lüppo-Cramer⁸⁵ by reduction of silver nitrate with elon (metol) and sulfuric acid. Except for a few large flat plates, it consists chiefly of small crystals, readily discernible at the highest magnifications. "Black" silver, however, produced with citric acid in place of sulfuric, could not be resolved with the optical microscope. Electron micrographs show it to consist of clusters of ultra-microscopic crystallites. (Fig. 15b)

It is probable that the difference is due primarily to the rate at which initial nuclei are produced, which rate appears to be much decreased in the presence of the stronger acid.

Related effects in the field of silver reduction, known to the colloid chemist, are the production of varicolored colloid silver by changing the amount of innoculating colloid metal, gold or silver, in a reducing system⁸⁶ and, known to the photographic chemist, the production of warm tones with gelatino-chloride papers by restrained

* Failure to observe this condition has led to erroneous conclusions as to the effect on speed at the same gamma: *e.g.*, G. Schwarz: *Phot. Korresp. Belge*, No. 1, p. 1 (1934).

FIGURE 15a. Photomicrograph of "gray" silver. b. Electron micrograph of "black" silver, showing clusters of minute silver crystals. c. Electron micrograph of clumps of silver crystals in precipitated "black" silver.

development—using ammonium carbonate and ammonium bromide—and greatly increased exposure.⁸⁷ The effect of the latter is to secure increased number of nuclei, of the former, to secure independent "physical" development of these.

A Note on Graininess and Granulation

It is perhaps unfortunate that the term "grain" had already been applied to the ultimate crystallites of the silver halide emulsion and the developed image before the coarser phenomenon of "granulation" or "graininess" received adequate recognition. Whereas the units in the former case are preëminently single crystallites from perhaps 0.001μ to $3\sim5\mu$ in size, requiring either the electron microscope or the highest powers of the optical microscope for their discrimination, "graininess" is discernible at magnifications even of 10 to 30 times. It is a phenomenon above all of a statistical character—corresponding somewhat to the conception of second and third order aggregates in colloid chemistry.

Grain size distribution of *completely* chemically developed grains will tend to follow that of the grain size distribution of the original silver halide crystal,⁸⁸ although with some distortion, due to local deformations, enlargements, and coalescences. A generally valid distribution function for silver halide precipitates and simple emulsions is that for a skew probability distribution:—

$$y = Ae^{-\log(x-a)^2} dx$$

where y is the frequency of class-size x , dx or Δx is the width of the class-size unit used, a is the mean value, and A is a constant. It is not easy to test the relevance of such a function for even fully developed grains, because of (a) the irregular and indistinct shape of most grains with ordinary development (b) the tendency of many of the developed grains to break up and disperse on preparing a one-grain layer.

Again, any derived distribution for complete development ($\gamma\infty$) has only a limited relevance to the normal developed photographic image, at say $\gamma = 0.6$ to $\gamma = 1.2$, because so many will be incompletely developed. The fact is that *sensitivity* is not solely and simply proportional to grain size (or projective area) but that any class-size of grain has a two-fold variation of sensitivity due to (i) distribution of sensitivity centers, *e.g.*, silver sulfide nuclei (ii) position in depth of silver halide grains of emulsions. The latter can be plausibly represented by an empirical exponential

function⁸⁹ but while (i) is no doubt a probability function, there is no way at present of ascertaining it.

In most developers, the most sensitive grains will be the first to start to develop and therefore at a given stage of development (γ) will be giving the relatively greatest amount of silver. Since, on the whole (though with considerable variation, as stated) the largest grains are the most sensitive, the least exposed areas of the image tend to be composed of these, in diminishing proportion as the exposure increases. This is borne out by investigations on the "covering power" (C.P.) of chemically developed silver deposits.⁹⁰ The "covering power" is the reciprocal of the mass of silver per unit area which gives an optical density $D = 1$, where D is defined as $D = \log 1/T$, and T , the transparency, is the percentage light transmitted. However, since the developed image has more or less scattering power, distinction must be made between *diffuse* density measured by completely scattered light, $D_{\#}$, and *specular* density measured by and for parallel collimated rays D_{\parallel} . Only incomplete approach can be made practically to these extremes, but the usual densitometers measure approximately $D_{\#}$.

In the case of (chemical) development with hydroquinone James found over a considerable range of exposure when development was carried to completion a constant ratio for D/Ag . This agrees with the results of an examination of the image on ultimate development of a pure silver bromide emulsion by three different developers, *viz.*, *p*-aminophenol, pyrogallol, and metol (elon)-hydroquinone (cf. Fig. 16). It will be seen that there is no very considerable variation of the C. P. = $1/P.E.$ over the whole range of exposure. However, the significance of this must not be overestimated, since the fog values were high, notably with the pyrogallol and metol-hydroquinone, and this tends to equalize the C. P. values. With short development (Fig. 16) the C. P. shows a tendency to fall off to a shallow minimum, after which it rose slowly, approaching constancy in the overexposed region of the characteristic curve.

In a fuller investigation of covering power in relation to exposure and development⁹⁰ for two regular emulsions, (Eastman *Commercial* and *Process* films) developed with standard *p*-aminophenol developer, it was found that the C. P. at any exposure *decreases* with time of development at first rapidly, then more slowly. This is in agreement with increase in average size of the developing grain. When C. P. was plotted against the logarithm of the exposure, it was found to *increase* with exposure and approximately linearly with the logarithm (Fig. 17).

A relation between photographic density, transparency, and average projective area of (developed) grains has been obtained by P. G. Nutting.⁹¹ According to this,* the transparency of multiple layer of n grains of average projective area a would be $T_m = (1 - a_1 n_1) (1 - a_2 n_2) \dots (1 - a_m n_m)$ the corresponding *absorption* $B_m = 1 - T_m$. If the layers are alike in number and size of grain,

$$T_m = (1 - a n)^m$$

when $D = -m \log (1 - a n)$. For sufficiently small values of $a n$ this gives $D = m (n a)$ where a is the average size of grain, and P , the photometric constant, should be equal to $k. d.$, where k is a constant and d the mean diameter of grains. Higson⁹² from similar considerations, came to the same conclusion.

In a paper on "The So-called Photometric Constant" J. Eggert and A. Küster⁹³ determined "mean grain diameter" in an indirect manner. They had previously concluded that the Callier constant $Q = D_{\parallel}/D_{\#}$

Where D_{\parallel} = density by parallel light

and $D_{\#}$ = density by diffuse light

stood in a simple relation to the mean grain diameter d , which could be expressed

* Probability reasoning for the snow-flake problem.

FIGURE 16. P.E.—photometric equivalent for different developers for long and short development.

as d (measured in μ) = $K \log Q$, where K was a constant for a given photometric apparatus. Using this relation to establish the "mean diameter" d of certain developed densities, they found, on measuring analytically the mass of silver, that $P = A + Bd$ where A and B are constants. This they established for different types of emulsion, and different times of development. The diameter d here considered is presumed to be the (arithmetic) mean for the ultimate silver grains. There is a rather peculiar corollary to this in respect of "graininess." In other investigations,⁹⁴ Eggert and Küster concluded that the "graininess" G_s (found subjectively by relative enlargement) could be equalled to a multiple of $\log Q$; hence there should exist simple proportionality between "graininess" G_s and the ultimate mean grain diameter. This simple relationship has been considerably criticized chiefly in respect, however, of the asserted relation

$$G_s = 100 \log Q.$$

A physical measure of "granularity" might be expected by scanning a given area of a uniformly illuminated and developed layer with a microphotometric device of

FIGURE 17. C.P.—covering power, as function of exposure and time of development.

sufficient resolving power.⁹⁵ Assumption of a Gaussian probability function for representing the transparency fluctuations could lead to a “granularity” constant expressing a standard deviation (Fig. 18). If the distribution is Gaussian, then

$$\Delta T/T_m = x,$$

the relative transparency fluctuation, is expressible by an error function of the form

$$(a/G_a\sqrt{\pi}\int_0^x \exp. -(x/G_a)^2dx$$

with the single parameter G_a measuring the “granularity.” Actually, the distribution of fluctuations appears to be somewhat skew as in the case with the distribution of grain-size.

FIGURE 18. Micro-densitometric fluctuations of developed image.

The relations between the physically measured granularity and the subjectively perceived "graininess" are outside our subject. It may be pointed out, however, that "graininess," as a visual perception, is conditioned by various factors such as field area and field brightness, contrast and so forth. The psychological integration of the various and variously modified thresholds to a "gestalt" is unlikely to be representable by a physically measurable single parameter, nor even by an explicit function of physically defined variables. The position is similar to that discussed recently by G. W. Scott Blair,⁹⁶ for certain tacomuscular perceptions, such as "firmness" and "plasticity."

In conclusion there is some interest in contrasting the simplest form of "physical" development, with the simplest form of "chemical" development. The former we have noted as daguerreotype. It consists in the preferential adsorption of mercury atoms to the "latent image" of silver iodide on silver metal. It is hardly doubtful that we have in this case preferential adsorption to silver nuclei, the subjacent silver base having accepted the iodine photolytically released. The phenomena of mercury vapor sensitization^{96a} and mercury vapor intensification of the latent image on gelatino-silver bromide are continuous with this, and indicate a direct bridge between this simplest type of "physical" development and the complications of chemical development. It must be assumed, in this latter case, that adsorbed mercury atoms form an effective catalyst for chemical development. That these mercury atoms are oriented and polarized by the original nucleus surface is probable⁹⁷ but equally must it be concluded that they deform and activate silver ions of the adjacent silver halide, and that it is just here that the external developer commences its attack. Very possibly this is concomitant with an extension of Huggins' B3 ~ 4 region in the silver chloride or bromide; this may be an important part of what is somewhat glozed over by the term "activation of the silver ion"—which would consist largely in its loosening from the constraint of the B1 lattice.

The smallest form of "chemical" development is exhibited in the *thermal* development of various endothermic compounds, such as silver oxalate, thallous oxalate, mercurous arsenite, and mercurous oxalate. These compounds do not absorb in the visible region, but after exposure in the near ultraviolet a latent image may be developed by heat alone, the rate of development increasing with the temperature.⁹⁸ There is no extraneous substance implicated, neither from a gaseous phase nor from a solution. The development or decomposition proceeds at the interface between the metal and the undecomposed crystal, the ion or radicle C_2O_4 disappearing as CO_2 —gaseous carbon dioxide. The example of mercurous oxalate is perhaps outstanding, since there can be no question of a new lattice of mercury atoms—no more than in the comparable case of the chemical development of mercurous chloride.⁹⁹ There is little or no evidence for migration of mercury ions, nor of silver ions with silver oxalate. The probabilities are definitely in favor of movement of mercury or silver atoms in the extension or prolongation of the interface, both from the very poor or negligible electrolytic conductivities of these substances, and from the absence of any internal or impressed e.m.f.* Although migration of ions seems not to be necessary for development to occur in the solid crystalline phase, this is not to say that it may not occur to some extent in the silver halides, where the conditions may be more favorable for that mode of decomposition. So far as we know, there is nothing in thermodynamics which prescribes the kinetics or the path by which an inevitable increase of entropy shall be secured—nor the time in which it shall be attained. From this point of view, the chemistry and physics of colloids have to do

* This simplification of "chemical" development need not exclude the scheme of James and Kornfeld¹⁰⁰ for the reaction-complex in "chemical" development. In terms of this, D, the developer, is here the radicle or ion $= C_2O_4$, which is the equivalent of the various complex forming ions or molecules previously discussed, such as the di-hydroquinonate ion, hydroxylamine, phenylene diamine, ferrooxalate anion.

in the main with systems transitorily arrested in the attainment of the ultimate thermodynamic nirvana. Photographic development is an enlightening example.

Acknowledgment

Beside acknowledgment to many colleagues mentioned in this article, I wish also to express my thanks to Dr. R. H. Lambert of the Eastman Kodak Research Laboratories for assistance in the determinations of heats of development, to Dr. C. E. Kenneth Mees and the editors of various journals for permission to reproduce certain figures from papers published from the Eastman Laboratories.

Liesegang Rings

ANDREW VAN HOOK

Department of Chemistry, Lafayette College, Easton, Pennsylvania

In 1896 R. E. Liesegang^{1a} discovered that if a gelatin gel of dilute potassium chromate is inoculated with a crystal or strong solution of silver nitrate, the resulting precipitate forms in a discontinuous and periodic pattern, which form has since been known generally as "Liesegang Rings." Although Liesegang was not the first to observe such rhythmic precipitations,² it was his extensive study and descriptions^{1b-d} that directed attention to, and stimulated much speculation and work on, this rather spectacular and impressive phenomenon.

The general conclusion of the prodigious amount of work following Liesegang's original announcement is that the phenomenon is not specific, but seems to be general for any deposition of matter under constrained conditions. Thus, almost all precipitation reactions³ may be conducted to form a rhythmic structure. Most workers agree that a rigid medium, such as that afforded by a gel, is not necessary,⁴ but it assists by providing a framework to stabilize or fix the resulting structure. Not only precipitates formed by metathesis, but crystals formed from melts or solvents,^{5, 6} solids settling from suspensions,⁷ coagulants of colloidal suspensions^{8, 9} etc.^{10, 11, 12} are liable to periodic development. In quantitative aspect the time, t_n of appearance of any band, n , and its displacement, Y_n , are quite accurately designated by the expressions:

$$\frac{Y_n}{\sqrt{t_n}} = k$$

and

$$\frac{Y_n}{Y_{n-1}} = k'$$

These ratios and various other relations are known by various names,^{17d} but are perhaps best designated as the Morse and Pierce²⁰ and Jablynski²⁹ constants respectively. Slight deviations from constancy are observed in the early and late parts of any particular experiment, but these variations may be accounted for.^{17b} The abundant literature up to 1932 is presented in review by Hedges¹⁰ and by several others.^{11, 12}

With the plentiful data available on the Liesegang phenomenon, most of which is, unfortunately, only qualitative in nature, it was quite natural that no single proposed theory and mechanism was adopted universally. Hedges¹⁰ mentions four principal theories extant at the time of his review. Since serious objections to all four of these theories are recognized, he prefers not to emphasize any one explanation, but suggests a general theory which describes and incorporates the essential features of all. He suggests that for the deposition of a rhythmic structure there must first be realized a critical condition (which he does not specify) followed by a mobilization of material forming the structure. It is apparent that this situation is common

to the following four theories and suffers by its generality and lack of exact mechanism.

(1) **Supersaturation theory of Wilhelm Ostwald.**¹³ Ostwald suggested that as the diffusion wave of inoculant advanced through the solution a concentration of precipitate in excess of saturation was formed as a consequence of the tendency to supersaturate. When this concentration reached the "supersolubility," a concentration of spontaneous crystallization, the precipitation spread backward in its course to the solubility limit. Simultaneous depletion of reactant by counter-diffusion in advance of the precipitation front clears this area, thus preserving a well-defined precipitation front, and creating a clear area which must be traversed by the inoculant before the action is repeated.

(2) **Wolfgang Ostwald's theory**¹⁴ is essentially an extension of his father's, in which the diffusion of the soluble products of reaction play a magnified role. These effects are of great significance in some cases¹⁵ (i.e., $\text{NH}_4\text{OH} + \text{MgCl}_2 \rightarrow \text{Mg}(\text{OH})_2 + \text{NH}_4\text{Cl}$), but they may be considered as secondary. Thus this theory reduces essentially to the disturbed diffusion mechanism of the supersaturation theory.^{42, 25}

(3) **The Adsorption Theory of Bradford**¹⁶ attributes the clear spaces between the rings to the lack of reactant removed by adsorption. The objections to this theory are that adsorption of this kind has never been demonstrated;¹⁰ many experiments are known in which adsorption effects are unlikely;¹⁰ rhythmic precipitates may be formed when the rate of adsorption is much less than the rate of formation;^{17a} and lastly, there is no necessity to invoke such a marshalling effect as adsorption to account for the clear spaces in a periodic structure.^{17c}

(4) **A Modified Adsorption Theory** has been suggested by Dhar and Chatterji,^{1, 18} in which they relate the periodic nature of the structure to the periodic peptizing influence of the gel on the colloidal reaction product. This explanation is limited in its scope, since it is generally recognized that the phenomenon is quite independent of the medium, and also since the structures as laid down are often definitely crystalline,^{19, 5, 17b} and of appreciable particle size.

Attention is thus focused on the supersaturation theory of Wilhelm Ostwald, the first proposed to account for Liesegang rings. The three principal objections which have been raised to this theory are: (a) ring formation proceeds in the presence of seeds or nuclei of the ring-forming material; (b) supersaturation, prior to ring formation, has not been demonstrated; (c) supersolubility and a definite supersolubility product, H , as postulated by Wilhelm Ostwald and confirmed by quantitative measurements of Liesegang Rings,²¹ is a dubious concept.

Concerning the first objection, it was Hatschek²¹ who first observed that the lead iodide bands could be generated in the presence of seeds of the same material. He reasoned that supersaturation was impossible under this condition, and hence Wilhelm Ostwald's theory was ruled out. However, it has been observed^{17b, 22} that if sufficient seeds are present, ring formation is prevented. The more concentrated the reactants, the greater is the seed density required to prevent ring formation. Or, in a given circumstance with uniform seed distribution, extent of ring formation, X , (as measured by number or distance of ring formation) will be quite definite as a consequence of dilution of reactants as diffusion proceeds. Over a limited concentration range X depends upon n (seed density) in a hyperbolic manner. $nX^2 = \text{constant}$. This relation has been deduced^{17c} from Wilhelm Ostwald's formal theory²⁰ upon ascribing a definite rate to the growth of precipitating crystals.

Bolam,²³ Yanagihara,³⁷ and the author^{17b} have demonstrated in various direct and indirect ways that extensive supersaturation is realized in systems which form Liesegang Rings. For silver chromate in gelatin, ion products 1000-2000 times the ordinary solubility product are realized. Lead iodide and other systems in various media behave similarly.

In his original paper, and in applications²⁰ thereof, Wilhelm Ostwald suggest

that precipitation commenced when a very definite concentration in excess of saturation was reached. This "supersolubility"²⁴ was implied to be entirely analogous to the ordinary solubility, and signified the concentration above which a metastable supersaturated solution became labile or spontaneously crystallizing. A supersolubility ion product, H ,—a counterpart of the ordinary solubility product—has been assigned to define this concentration.^{20, 25, 17c, 26, 42}

Many objections^{14, 26} have been raised to this concept of a definite, static supersolubility limit, and a more general interpretation has been substituted. This condition consists of the rapid growth of existing and/or generated nuclei.²⁸ This kinetic interpretation has been applied to explain the Liesegang phenomenon.^{17f} In place of the supersolubility product H as definitive of crystallization, there is substituted the condition that the rate of crystallization, at any point, increases as the concentration builds up by diffusion. This rate is augmented by the presence of nuclei of the precipitant. The positions and times of appearance of the bands are correlated with the maxima, with respect to space and time respectively, of the net concentration resulting from the opposing tendencies of diffusion and crystallization. To carry through this computation, information on the rate of crystallization of the precipitate is required. Such data have been determined for silver chromate in water and gelatin,^{17g, h} and the calculations performed in an approximate manner.^{17b} The results confirm the usual quantitative description of the Liesegang phenomenon, and also describe the behavior in the presence of seeds. This interpretation also indicates that any effect of a gelled medium will be primarily through its effect on the rate of crystallization, since diffusion rates remain essentially unaltered. This has been confirmed qualitatively^{17a} by observing the time and spacial characteristics of definite precipitations in various media. Quantitative confirmation would require the kinetic data on the rates of crystallization in the various media.¹⁷ⁱ

In 1934 Christiansen and Wulf identified* the average motion of the diffusing particles with the velocity in the de Broglie equation, $\lambda = \frac{h}{mv}$, where λ is the wave length or distance between rings, v the diffusion velocity, m the mass of the diffusing particle, and h Planck's constant. Further application of Schrodinger's equation results in approximate formulas which seem to account for the observed Liesegang phenomenon, although Christiansen and Wulf in their original publication did not find the agreement too good. The discrepancy is explicable^{17d} if an extrapolated number of rings, instead of the uncertain number observed, is compared with the number calculated. The agreement is also improved if one eliminates hydration of the salts used,³¹ or corrects for it in the computation.³²

This new interpretation of the Liesegang phenomenon has been extensively and successfully pursued by Shemyakin and his co-workers,³³ and others.^{34, 36} The wave-mechanical analogy is complete, and the analysis profits by eliminating a detailed model and exact mechanism. Shemyakin finds that the product (λv) retains its value within close limits for all periodic reactions in gels. The interpretation is a complete indorsement of the supersaturation theory already described, with the advantage of suggesting methods of computing the various characteristic constants of a series of bands. Various secondary systems of rings³⁶ and distorted figures³⁵ have been explained qualitatively and quantitatively as interference and refraction patterns. The formal and detailed supersaturation theory is perhaps superior in explaining results when the rate of crystallization is strongly influenced by nuclei already present.

The rather common occurrence of the deposition of matter in a periodic fashion

* That is, if the Morse and Pierce and Jablonski constants are combined in the Bauer form,^{17d} $\frac{\Delta y}{\sqrt{\Delta t}} = k''$, and then considered as $\frac{\Delta y}{\Delta t} \cdot \Delta y = (k'')^2$; the first factor is identified with v , and the second with λ .

has suggested some very interesting and at times fanciful correlations with the Liesegang phenomenon. An immediate and apparent example of a naturally occurring periodic structure is the agate^{1c} and other geologic formations.³⁸ The banded structure of gallstones and other concretions, the markings on wasps' wings, the rhythmic swarming of bacilli, beet root markings, (annual) tree rings, the structure of boli or pasture droppings ("fairy rings"), etc.,^{10, 17e} have all been cited as examples of

FIGURE 1. Regular bands of Silver Chromate in gelatin gel. From A. W. Thomas—*Colloid Chemistry*, N. Y., 1934.

FIGURE 2. Spiral form of Liesegang rings. Silver Chromate in gelatin gel. From A. W. Thomas—*Colloid Chemistry*, N. Y., 1934.

Liesegang rings. One cannot deny that all these structures are the result of disturbances in the generating systems; but if one takes as the criterion for the true Liesegang phenomenon the constancy of the Morse and Pierce and Jablonski ratios, then all but the agate and other geologic formations are definitely excluded from this classification. And in all these examples there is no particular need to involve the Liesegang phenomenon in explanation, since more reasonable explanations are evident.^{17e}

The rather peculiar forms sometimes assumed by periodic precipitates, such as

spirals,³⁹ incomplete bands,⁴⁰ repeating bands,^{17b} etc., may be explained as the result of particular conditions of interrupted diffusion or other disturbances. It is not unlikely that temperature or concentration gradients may cause some of these unusual effects.

A very good application of the Liesegang phenomenon has been suggested by

FIGURE 3. Partial bands of Cobalt Hydroxide in gelatin. T. Moeller—*J. Chem. Ed.* Nov. (1940) p. 519.

FIGURE 4. Zone pattern cut from center of ferrocyanide impregnated cake of gelatin after immersion in copper sulfate solution. E. R. Riegel and L. Widgoff—*J. Phys. Chem.* 29 872 (1925).

Bucher,⁴¹ who has devised a new method of blood analysis depending on the sensitivity of Liesegang Ring formation to very slight variations in blood composition and quality. Liesegang¹ has discussed the production of artificial pearls by diffusing alkali phosphate into a calcium salt. The writer has produced a few pieces of novelty ware by generating periodic systems in media which could be hardened and fixed by tanning.

Fixing the Dates of Past Events by Tree Rings and Varves *

CHESTER A. REEDS

During the first four decades of the 20th century tree-ring and varved clay chronologies were developed and are now being used in dating various events. These time-tables are based on various kinds of natural evidence—different colloidal deposits developed under conditions quite remote and distinct one from another. They have the year, however, as their unit of measurement and in this respect are of importance to science. They overlap and supplement one another, in part, and have been joined to our own historical (Julian) calendar. Seasonal changes affect plants and trees and even sediments laid down under water. The tree-ring and varved clay chronologies are based on seasonal changes and represent much field and laboratory work by various men working in widely separated areas.

The growing period of trees occurs in spring and summer and their resting or maturing stage in autumn and winter. Soft white cells grow at a rapid rate in the spring. The growth is dependent upon the relative amounts of snowfall and rainfall of the preceding winter, as well as upon the nature of the soil—whether porous or compact—and its depth. In the autumn, because of lowered temperature or diminished water supply, there is a gradual cessation of the activities of the tree. This change is recorded by the deposition of denser and darker material in the cell walls. During the winter, growth practically stops. The seasonal changes are thus recorded in the annual rings of trees.

Years deficient in rainfall or lowered temperature are more noticeable and more widespread than favorable years, for a deficient year is characterized by an individual ring that is thin compared to those beside it. A group of thin rings represents a drought period. Thick rings are more likely to come in groups, and are not so extensive geographically as thin rings. Variations in climate can thus be detected in the growth rings of trees. Successive years are not alike, for variable factors, such as the annual amount of snowfall, rainfall, degree of temperature and length of growing season, affect the amount of tree growth.

The tree-ring chronology is primarily the work of Dr. A. E. Douglass, Professor of Physics and Astronomy in the University of Arizona. For many years, as an astronomer, Douglass made a study of sun-spots. There is a periodicity in this phenomenon which is reflected in tree growth. As an aid to sun-spot investigation Douglass studied trees, for, as he says, solar changes affect our weather and weather in turn affects the trees. In regions where moisture is abundant in the soil there is often noticed a beautiful rhythm of annual rings which corresponds to the sun-spot cycle of 11.4 years. Other cycles of 6 years, 22 years, 35 years and 100 years have been noted. In fact, successive centuries may have different combinations of climatic cycles.

In the pine trees of the semi-desert areas of Arizona, Douglass found evidence of

* The deposition of tree-rings and of varves (laminated deposits of glacial clays) involve colloid-chemical principles. Scientific interpretation of these deposits has revealed important chronological data. Editor

the eleven year sun-spot cycle recurring periodically for 500 years, except for the years 1650 to 1725. During this interval the tree rings afforded no evidence of sun-spots. This was separately confirmed by the English astronomer E. W. Maunder, who discovered that there were no sun-spots between 1645 and 1715.

The next tree-ring problem undertaken by Douglass was a study of the pines of northern Arizona for evidence of climatic effect of drought. This work resulted in the identification, dating and measurement of more than 100,000 rings in nearly 400 different trees. In pine trees near Prescott, Arizona, Douglass, in 1911, established cross-identification of tree rings, the yearly identity of the rings and the climatic character of their major variations. Of the climatic character he says: "The extent of area over which this extreme similarity is found may be only a half mile, as in the mountain regions near Prescott, or 50 miles as found between groups in the Sequoia region, or even more than 200 miles as shown between Flagstaff, Ariz. and Durango, Colo. Occasionally rings of extreme character are found to be alike in the Sequoias of California and in the pines of Arizona, 450 miles away. Very rare rings have been traced across 750 miles of country."

In 1915, Douglass, in response to a letter from the anthropologist Dr. Clark Wissler of the American Museum of Natural History, New York, studied some beams from cliff dweller ruins in New Mexico. These beam sections were compared with surrounding trees and from trees growing in ruins, and it was evident that pine and spruce beams were very good for this study, but that juniper was often very disappointing.

In 1918 additional beam specimens were studied: six from Aztec, N. M., and three from Pueblo Bonito, in Chaco canyon. Three or four of those from Aztec afforded cross-identifications. Later, in 1919, Douglass visited Aztec and found that the sections which he had examined had come from a pile of loose beams whose exact location in the ruin was not known. Since this was desired, Douglass devised a set of core-boring tools from steel tubing, and with this apparatus cores were obtained from some 26 beams, located in 16 different rooms, without injury to the ancient building. In time, tree-ring records of some 37 different beams from Aztec were obtained, cross-identification established and the relative dates of the cutting ascertained. He says: "Nine years covered the time of cutting the various timbers examined from Aztec." These were then compared with beam sections from Pueblo Bonito, with the result that cross-identifications between these ruins were established. Of this study Douglass says (1921): "There is no doubt that the beams in Aztec and Pueblo Bonito were living trees together during more than a hundred years and that the cutting of the timbers for Aztec followed that for Pueblo Bonito by from forty to forty-five years." While the relative dates of these two ruins were thus determined, their actual dates in our chronology were not to be announced until much further work had been done.

From 1921 to 1929 the National Geographic Society conducted eight and Douglass three expeditions in the study of the cliff-dweller ruins of the Southwest. After codifying the results of the study of tree rings in many ancient beams, some of which had been burned and were in charcoal form, Douglass, in a most interesting article in the December number of the *National Geographic Magazine* (1929), announced that he had succeeded in developing a continuous tree-ring chart for the Southwest, starting with 1900 A.D. and running back to 700 A.D., that is, for 1200 years. He also dates in terms of our own calendar the great prehistoric communal dwelling of Pueblo Bonito, containing some 300 rooms, and also some 40 other ruins in that desert-plateau-canyon country surrounding the four corners of Utah, Colorado, Arizona and New Mexico. The age of these ruins has long been a problem that the archaeologist would like to have solved, for he has found much of interest therein.

In endeavoring to find the date of construction of the communal dwellings in the various ruins, Douglass found that some of them were under construction at differ-

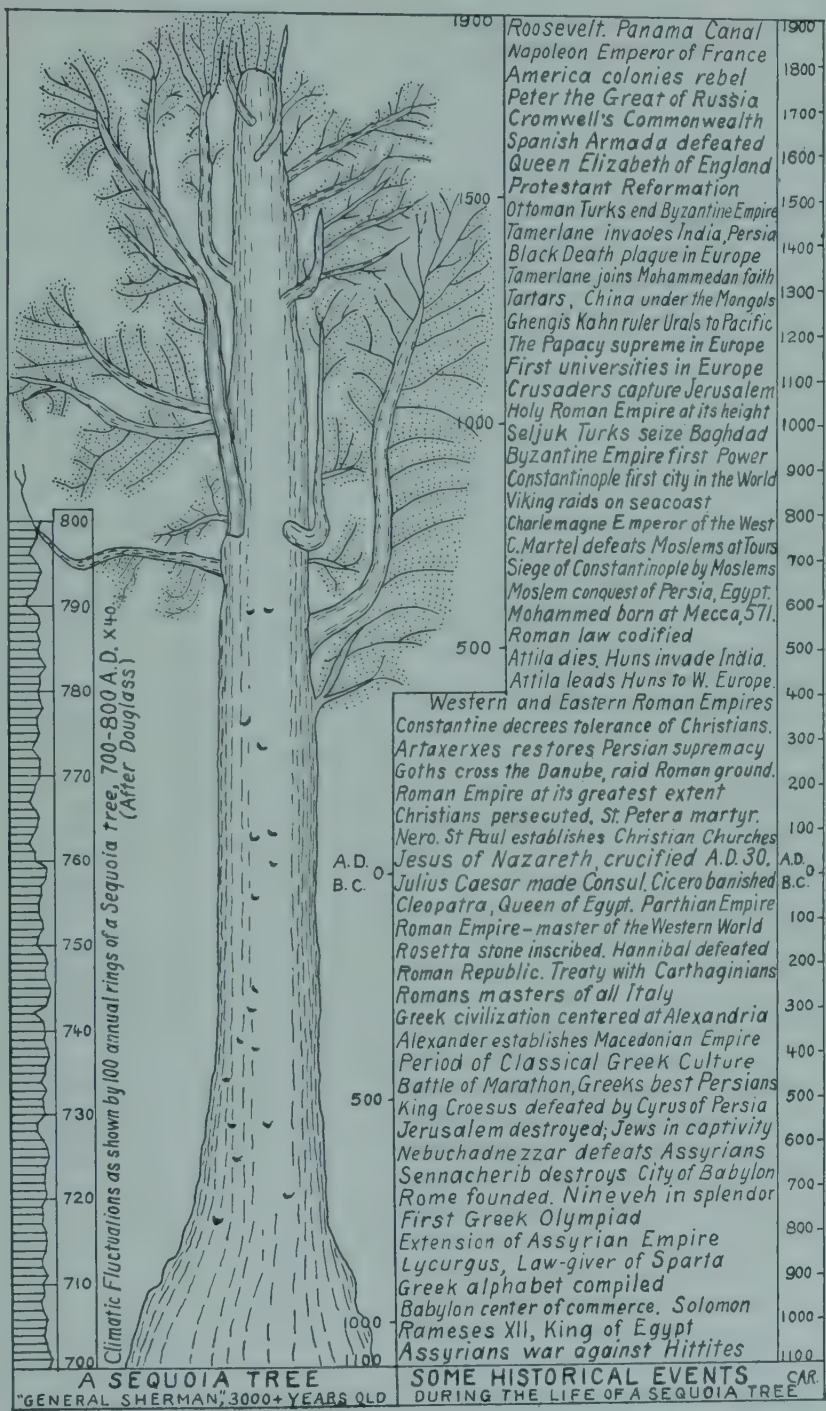

FIGURE 1.

ent times, as in Pueblo Bonito, in Chaco canyon, New Mexico. This is also the oldest of the ruins according to the tree-ring story; for one of the beams, cut in 919 A.D., shows that it started to grow as a tree in 700 A.D. Douglass gives the age of the following named ruins: Pueblo Bonito, N. Mex., 919-1130, under construction at different times: 919, 1017, 1033-1092, 1102 and 1130; Sliding Ruin, Ariz., 936-957; Pueblo del Arroyo, 1052-1103; White House Pueblo, Ariz., 1060-1096, 1219 and 1275; Mesa Verde, Colo., 1073-1262, including: Cliff Palace, 1073, Oak Tree House, 1112, Spring House, 1115, Balcony House, 1190-1206, Square Tower House,

1204, Spruce Tree House, 1216 and 1262; Wupatki, Ariz., 1087-1197; Solomon, N. Mex., 1089; Aztec, N. Mex., 1110-1121; Cliff dwellings in Grand Gulch, Utah, 1133-1135; Klag-E-Toh, Ariz., 1162; Sholow, Ariz., 1174-1383; Fewkes Ruin J, Ariz., 1192; Citadel, Ariz., 1192-1260; Pinedale, Ariz., 1200-1320; Turkey Hill Pueblo, Ariz., 1203-1278; Mummy Cave, Ariz., 1253-1284; Betatkin, Ariz., 1260-1277; Keet Seel, Ariz., 1274-1284; Kintyel (Wide Ruin), Ariz., 1275; Kawaiku, Ariz., 1284-1495; Oraibi, Ariz., 1370-1800; Chaves Pass, Ariz., 1381; Shongopovi and Shipaulovi, Ariz., 1390-1800; Kokopnyama, Ariz., 1410; Walpi, Ariz., 1427-1605.

It should be noted here that, while Douglass was fitting his tree-ring calendar together and for a long time before that, the historical period in the Southwest began with the date 1540, the year when the first Spanish expedition came into that region. In that year Indians in the Southwest were living in large communal houses just as the Hopi, Zuni, and other tribes about Santa Fé dwell in their pueblos today.

While assembling the parts of his tree-ring chronology, Douglass found that the years 840, 1067, 1276-1299, 1379, 1632 and 1880-1904 were years of excessive drought in the plateau country of the Southwest. These drought-year registrations were of great assistance to him in determining the cutting date of the numerous timbers used in the construction of the various cliff houses and communal buildings. The people who erected and lived in these abodes were primarily agriculturists with weaving and pottery making as important industries. The women were masters of the home and the men of the fields. Turquoise was not only highly prized for ornamental purposes but also as a means of exchange, and for appeasing the spirits.

The longest record of tree growth is that found in the "Big Trees" of California, the *Sequoia washingtoniana*. These trees average 275 feet in height with a diameter near the ground of 20 feet; and specimens from 300 to 320 feet tall, with trunks 25-35 feet thick, have been found. There is a moderate-sized section of one of these trees in the American Museum of Natural History, New York. The tree was cut in 1894. A count of its annual rings, most of which are about a millimeter in thickness, shows that it started to grow in 550 A.D., and was thus 1344 years old when cut. The growth rings in the stumps of some large Sequoias have been counted by A. E. Douglass and Ellsworth Huntington. Huntington counted the annual rings in 79 trees that were more than 2000 years old and in 4 that exceeded 3000 years. In regions which have climates similar to California, such as the Mediterranean, it is possible to compare the "Big Tree" record with the rise and decline of the great governments of the countries bordering the Mediterranean from about 1300 B.C. to the present. This has been done by Ellsworth Huntington for the American Museum exhibit. In his book "The Climatic Factor," Huntington makes frequent reference to the rings of growth of the great Sequoia trees, which he states give an approximate record of climatic changes that is fairly reliable for two thousand years.

A longer annual record than that afforded by the living Sequoia trees has been obtained in Sweden, and other parts of the world, from the glacial clays deposited in fresh-water lakes which bordered the retreating ice front of the last continental glacier. On close inspection these glacial clay deposits show distinct seasonal layers or bands: a summer layer, which is the thicker, of more sandy material, and of lighter color, usually gray; and a winter layer, which is the thinner, of very fine clay and of dark bluish or reddish color, depending upon the color of the rock from which the clay particles were derived. In passing upward from a dark winter layer to the succeeding coarse gray summer layer, the change is abrupt; from the summer layer to the winter layer, however, the change is gradual. The coarse summer layers have very fine lines of bedding, while the winter layers are homogeneous and uniform in appearance. The seasonal layers alternate in position without exception

throughout a clay bed. A pair of such layers representing an annual deposit is called a varve.

The clays are of glacial age, since each layer had its origin in an annual retreat stage of a melting glacier. They were developed as follows: As the ice melted and retreated slowly northward during the warm summer months of each year, the swollen rivers which flowed out from under the ice mass picked up the fine sand and clay particles and transported them to fresh-water lakes which occupied the lower portions of enclosed basins in front of the glacier. As the stream currents, on entering the still waters of the lake, gradually lost their power to transport their load of sediment, the fine sand and coarse clay particles settled down over the lake bottom to form the sandy summer layer. During the cold winter months of each year the ice-front became stationary, the englacial and subglacial stream courses either ran dry or froze, and little, if any, sediments were transported by the rivers flowing into the lake. The surface of the lake also became encrusted with ice and snow, and the fine clay particles, which had been held in suspension in the milky waters following the summer incursions, slowly settled to the bottom to form the bluish, reddish or dark winter layers composed of pure clay. Before the end of the winter season, the lake waters cleared, and a sharp line of demarcation was established between the top of the winter layer and the base of the succeeding summer layer. This well-defined line is of value in grouping the seasonal layers into varves.

Variations in the thickness of succeeding varves indicate that there were fluctuations in the amount of melt water and volume of sediment delivered to the lake basin. These features were governed no doubt by the daily, seasonal and annual changes in the weather. The varve for a particular year, however, is of approximately the same relative thickness at any designated level in the lake basin. Where there are high and low levels covered by the lake waters, the varves are thinner on the higher elevations than on the lower. Another circumstance of considerable note is that the varves overlap one another very much like shingles on a roof. This too was brought about by the amount of summer melting and the annual retreat of the ice front. The location of the limit of each varve, that is, where it touches the bed rock, enables one to determine, where practicable, the position of the ice front for a particular year, as well as the rate of retreat.

In Sweden the rate of glacial retreat was irregular—in the south in Scania and Beleking about 75 meters a year. Before reaching the two great Fennoscandian moraines near Stockholm, which represent distinctly adverse climatic conditions for a century each, it increased to 100 meters. North of the great moraines the retreat fluctuated from 100 to 300 meters or more a year, and only occasionally was it interrupted by a stoppage or small advance.

The retreat of the last glaciation in Sweden may be subdivided and summarized as follows: The dates and time given are according to Gerard De Geer, Stockholm, 1940.

(1) *Daniglacial*: Part of Denmark, part of Scania, and north central Germany south of the Baltic moraine. Time undetermined.

(2) *Gotiglacial*: Retreat from the terminal moraines in middle Scania to the southern border of the great Fennoscandian moraines south of Stockholm, 13100 B.C. to 6721 B.C., or 6379 years.

(3) *Finiglacial*: The retreat from the southernmost of the Fennoscandian moraines to the parting of the land ice into two parts in the Ragunda district, 6721 B.C. to 5642 B.C., or 1073 years.

(4) *Postglacial*: of Swedish geologists, based on the work of R. Lidén in the valley of the river Angermanälven, 5642 B.C. to 1900 A.D., or 7542 years. The above figures give a total of 15,000 years for the retreat of the land ice from central Scania to the present small ice caps in north central Sweden.

The glacial clay studies in Sweden have been made chiefly by Baron Gerard De Geer and a number of younger men trained by him, particularly Drs. E. Antevs, C. Caldenius, R. Lidén, E. Norin and E. Nilsson. It was in 1878 that De Geer was struck by the regularity of the clay laminae, which reminded him of the annual rings of the trees. The next year he commenced his investigation of the Swedish clays. In 1882 he advanced the view that there might be a close connection between the periodical laminae of the clay and the annual retreat (ablation) of the land-ice. In 1884 he was convinced that the laminae were really annual; and having developed a method of correlating annual layers at different places by means of diagrams, he outlined a way by which a chronology of the last part of the Ice Age could be obtained. In 1885 he succeeded in making his first correlation between the clay layers at three points not very far apart.

De Geer's method of correlating the varves is as follows: In the field, a vertical section of the clay bank is smoothed and the thickness of the successive varves is marked on narrow strips of paper; then the recorded thickness of each is entered on a separate vertical line one-half centimeter distant and having a common base line, from which the measurements are laid off. When the tops of these vertical lines are connected, a saw-tooth curve results which practically shows the ups and downs of the different years, the very warm ones being shown by high summits in the curve, and the very cold ones by low notches.

In 1904 De Geer happened to get a very good correlation between two clay sections one kilometer apart. In 1905, with the assistance of 20 university students stationed one kilometer apart along a line 200 kilometers long, which ran in the direction of the ice recession, De Geer obtained, within four days, conclusive proof of the assumption that the individual varves had a very wide distribution, often exceeding some 50 kilometers. In 1906 with student assistance the line was extended to 800 kilometers. It then reached from eastern Scania in the south to S. Jämtland, the point where the last ice remnant became divided into two parts. This field campaign was successful, though at several places lacunae had to be left for clearing at a later date. The varve records having been obtained to a depth of about six feet, one kilometer apart, for 800 kilometers, it now became a matter of labor and patience for De Geer gradually to work out the chronology and climatic record.

To fill out the great gap between the late-glacial chronology and the historical one, De Geer and his wife in 1909 sectioned the postglacial sediments in the vicinity of Lake Ragunda, which was drained in 1796. Black-banded postglacial fjord clay yielded about 700 layers. This was followed by seasonal layers of alternating fine, sandy sediment and silt. Although the upper layers of the silt were somewhat obliterated by weathering, De Geer estimated that the postglacial sequence of layers represented about 7000 years.

In 1908, R. Lidén, one of De Geer's collaborators, found a periodically and evidently seasonal lamination in postglacial fjord-deposits along the river Angermanälven in Norrland. During the first year of study great difficulties were encountered; however, the investigation was continued.

In 1910, De Geer presented before the Stockholm meeting of the International Geological Congress an important paper on the results of his varve clay studies, entitled: "A Geochronology of the last 12000 years." At that time about 3000 years were allotted to the Gotiglacial stage, 2000 years to the Finiglacial and 7000 years to the Postglacial. The figures given were approximate, and not final, for the study of the varve records was still in progress.

In 1920, De Geer conducted an expedition to North America to investigate whether the Swedish Time Scale could be applied to late glacial clay deposits in the United States and Canada, and perhaps elsewhere in the world. The expedition, consisting of G. De Geer, Ebba Hult De Geer and assistants Drs. E. Antevs and R. Lidén, arrived in New York in August. The deposits in the Hudson and Con-

necticut river valleys, the shores of the Great Lakes and southern Canada were studied and the party returned to Sweden at the end of the year. Dr. Antevs remained behind to conduct further investigations in the United States and Canada. Many excellent exposures of varve clays were examined, and connections were established between long series of varves in Sweden and North America.

Although the last glaciation covered a larger area in North America than in Europe, the varve clay record, so far as studied, is represented by De Geer as enduring for about 7200 years, scarcely half that of the Swedish Time Scale. The American record is distributed as follows: 5000 years through the upper four-fifths

Courtesy Univ. of Toronto Press

FIGURE 2. Varves from clay belt in northwestern Quebec.

of the Gotiglacial stage, all of the Finiglacial stage (1073 years) and about 1200 years in the lower Postglacial stage. The terminal moraine on Staten Island and Long Island is interpreted by De Geer to be of Gotiglacial rather than Daniglacial age. The ice retreat from New York City to the northern line of New York State was accomplished, according to De Geer, in about 5000 years, that is, during the Gotiglacial stage.*

In 1924, De Geer organized the Geochronological Institute to house in Stockholm the already large collections and to further the varve clay investigations. Varve-collecting expeditions were also organized and sent out to distant countries as follows:

Dr. E. Norin in 1924 and 1925 conducted expeditions to the northwestern Himalaya mountains and collected varve series which correspond to the upper part of the Gotiglacial stage (—1318 to 1332). Dr. Carl Caldenius from 1925 to 1929 collected a large series of varves in Argentina and Chile which correspond to late Gotiglacial and early Finiglacial stages of the Swedish Time Scale. From 1932 to 1934 Caldenius found varves in New Zealand which tie in with middle and upper Gotiglacial varves in Sweden.

In 1927-1928 Dr. Erik Nilsson in British East Africa investigated and mapped the glaciations of Mt. Kilimandjaro, and secured from Rift valley lakes varves which could be identified with the early Gotiglacial, middle and late Finiglacial stages in Sweden. The earliest varves are associated with the archaeological finds of Dr.

* Considerable information about varves is to be found in "The Last Million Years, a History of the Pleistocene in North America," by Prof. A. P. Coleman (Univ. of Toronto Press, 1941).

S. A. Leakey, described as being of Aurignacian type. The age of these specimens is thus about 15,000 years. In 1928 varve series from the southwestern part of Iceland, collected in 1919, were correlated with the Swedish Time Scale and found to correspond to varves near the Goti-Finiglacial limit of the year -1073. In 1933 H. Lundberg in Newfoundland examined ice-lake varves which are of middle Gotiglacial age.

In 1928 and 1929 De Geer and his wife, Ebba Hult De Geer, made a series of varve measurements along the northern side of the Alps Mountains from Austria to France. Connections with the Swedish Time Scale were made for the early, middle and late Gotiglacial stage and the early part of the Finiglacial stage.

In 1940 De Geer published his "Geochronologia Suecica Principes," a more elaborate presentation of geochronology than has appeared in the 90-odd shorter papers by De Geer. The investigations of De Geer and eighty other geologists have been summarized here, the Swedish Time Scale has also been presented more fully, and workers in distant countries may now obtain a better understanding of this intricate subject. In the plates and tables all the different chronologies from various parts of the globe have been united into one common chronology of about fifteen millenia. It may be added that this volume deals primarily with Finiglacial material; the Gotiglacial series will be more fully represented in a volume devoted to that subepoch.

In the early part of this paper the tree-ring chronology, largely the work of Professor A. E. Douglass, was outlined. In the latter part the varve clay chronology, as developed by De Geer and his numerous collaborators, has been presented. In 1933 Ebba Hult De Geer made a comparison of a *Sequoia* graph, comprising 3020 years (1120 B.C. to 1900 A.D.), which was presented to the Geochronological Institute by Professor Douglass, with the corresponding part of the Swedish Time Scale. Several connections between the two chronologies have been reliably certified by this comparison, and the tree-ring *Sequoia* time scale, which falls within the historical period, has been included by De Geer in the Swedish Time Scale. The comparison of these two chronologies appears in the report of the 16th International Geological Congress, Washington, 1933. Although still in their youthful stages these two chronologies based on natural phenomena have already proved to be of value in dating past events. As time rolls on they will be found still more useful.

Part II
Biology and Medicine

Proteins *

W. T. ASTBURY

Textile Physics Laboratory, University of Leeds, Leeds, England

There is probably no subject more difficult to do justice to in one short article than that of the proteins, and we shall not attempt the task. Our aim must be simply to convey a quick idea of recent happenings, particularly from the viewpoint of x-ray analysis.

It is now generally agreed that proteins are polypeptide chain systems, alone or in combination with accessory groups or molecules, such as nucleic acids, polysaccharides, porphyrins, etc. The chains are linked by a variety of interactions between their side-chains and by less specific attractions between their backbones; above all, each protein owes its special properties not merely to the kinds and numbers of the amino-acid residues from which it is built, but also to the way the chains are folded or otherwise set up in space. Proteins are *organized* polypeptide chain systems: when the configuration of the chains is destroyed they become "denatured" and lose their specificity, even though accompanying changes in chemical constitution are usually of the slightest.

A first broad classification of the proteins would divide them into those that are visibly fibrous but not visibly crystalline, and those that are visibly crystalline but not visibly fibrous. To the first group belong such things as silk, hairs, tendons, muscle fibers, etc.; among the second we find egg albumin, insulin, hemoglobin, pepsin, etc. We should expect all proteins to be fibrous in some sense, just because there is so much evidence that they are composed of molecular chains, and because natural fibers are shown by x-rays to be of the nature of molecular yarns; but though the visibly fibrous proteins conform to expectations, as their description implies, the visibly crystalline ones seem not to do so, for their molecules in the native state are found by ultracentrifugal, x-ray, and other physico-chemical methods to be great rounded bodies—hence the name "corpuscular" or "globular" proteins. They betray themselves on denaturation, however, because then they all give similar x-ray photographs of the kind we have learned from fiber studies to associate with polypeptide chains, and the inference is that these chains have been liberated from their specific configurations and so manifest themselves simply as such. There is much other physico-chemical evidence, such as usually arise in viscosity, for this setting-free of peptide chains on denaturation; but the argument is clinched by the fact that it is possible to spin actual fibers from solutions of denatured corpuscular proteins, and these fibers when stretched give x-ray photographs analogous to those given by certain types of natural protein fibers.¹ What should be emphasized at once, therefore, is that it is now doubtful indeed whether there is any really fundamental distinction between the fibrous and the nonfibrous proteins: similar structural principles are used in the architecture of both, and as far as we can see at the moment, the difference is rather one of degree than of kind.

The fibrous proteins are the only ones so far that have yielded up to x-rays any appreciable *intramolecular* information: the inner structure of the corpuscular proteins is still mostly a matter of inference from that of the fibrous proteins. Many

* For a thorough-going treatment of this subject see "Proteins, Amino Acids and Peptides," by E. J. Cohn and J. T. Edsall, Reinhold Publishing Corp., 1943.

examples of the latter have been examined by x-rays and accessory methods, and it is remarkable into how few configurational groups they fall. The classical polypeptide chain, fully extended in the *trans*-form:

turns out to be uncommon. It is the normal configuration in silk fibroin, for instance, but most other protein fibers call for a wider interpretation. Even so, they still fall into probably only two main groups, the keratin-myosin group and the collagen group.

The problem of the keratin-myosin group is by way of being a prototype—or perhaps the prototype—problem in protein structure. The group includes not only the chief muscle protein, myosin,* but also the fibrous proteins of the epidermis of mammals, amphibians and certain fishes, and the fibrous structures, such as hair, horn, nails, etc., that arise from the mammalian epidermis.² All these are endowed with reversible, long-range elasticity, and all give two kinds of x-ray diffraction pattern according as they are unstretched or stretched. The normal form we have called α , and the stretched form β . As examples of the corresponding diffraction patterns, those of myosin, shown in Figures 1b and 1c, will serve as conveniently as any others, because the two types of pattern are constant throughout the group. This is not to say that the finer details are always the same—they are not—but it does imply that the main outlines of molecular structure are conserved, just as are certain characteristic elastic properties. The β -pattern is analogous to that of fibroin (Figure 1a) and corresponds to almost fully extended chains cross-linked through their side-chains to form polypeptide “grids” of the kind illustrated (purely diagrammatically) by Figure 2. A β -pattern may be obtained, too, from stretched artificial fibers made from denatured proteins,¹ and a beautiful elaboration of the β -pattern (Figure 1d) is typical also of the feather keratin subgroup of the keratin-myosin group, which includes, besides feathers, such structures as tortoise-shell, reptilian scales and the like. The *normal* state in the feather keratin subgroup is one in which the polypeptide chains are constricted to a length that is some 7 per cent short of their possible maximum, though it is possible to stretch them continuously and reversibly over this remaining 7 per cent.

The precise nature of the α -form and what happens during the reversibly elastic transformation to the β -form are the source of the great interest and importance of the keratin-myosin group, for the first promises the key to the intramolecular folds of the corpuscular proteins, and the second is probably no less than a particular manifestation of the molecular mechanism involved in the contraction of muscle.³ *Whatever the answers, they have to be independent of the marked variations in chemical constitution that occur throughout the group.* The α -form must consist of regularly folded polypeptide chains whose effective length, from other evidence, is approximately half that of the extended β -chains, and the folds in the main-chains must lie in planes perpendicular to the average direction of the side-chains. The latest and most generally satisfactory model⁴ is pictured diagrammatically in Figure 3: a detailed atomic counterpart to Figure 3 has also been constructed,⁴ but the diagram will suffice to illustrate the present discussion. It will be seen that the side-chains are grouped in triangular sets of three that lie alternately on one side and the other of the main-chain. The reasoning leading to this solution takes

* Footnote added in proof: It now appears that fibrinogen and fibrin also belong to the keratin-myosin group (Bailey, Astbury and Rudall—in press).

FIGURE 1. Five typical x-ray diffraction patterns of the fibrous proteins.

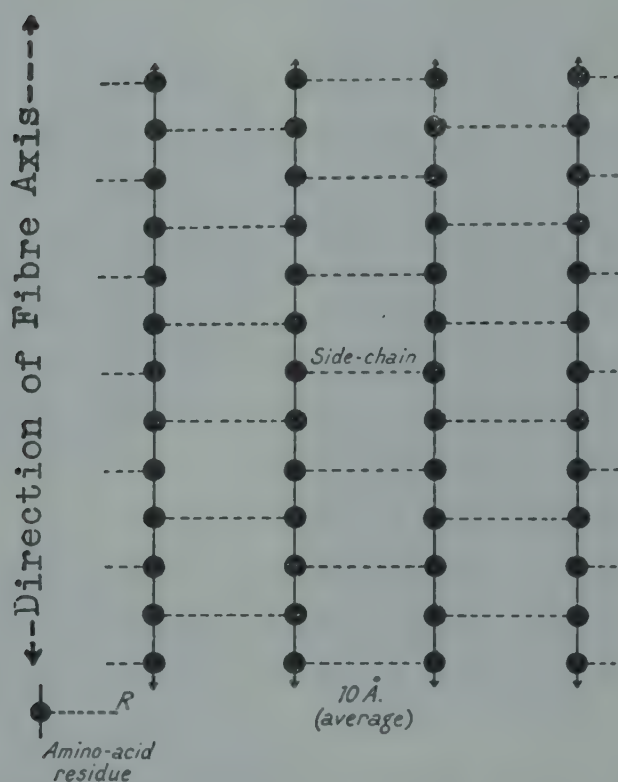

FIGURE 2. Diagrammatic representation of a polypeptide "grid" in the extended, or β , form. The α -form may be derived schematically by throwing the paper into a series of regular folds with crests parallel to the side-chains.

FIGURE 3. Packing of side-chains in the α -fold of the keratin-myosin group. — represents the direction of the main-chains; ● represents a side-chain pointing up from the plane of the diagram; ○ represents a side-chain pointing down from the plane of the diagram.

no immediate cognizance of the nature of the side-chains, which in a sense is all to the good; but it might be expected at least that the members of each triad should be similar to the extent of permitting or actively promoting aggregation: that is to say, that all three should be polar or all three non-polar. If this is so, then it follows also that *polar and non-polar side chains follow one another alternately along the main-chains*.⁵

Here in so many words is what promises to be the root idea of the whole keratin-myosin group. It is still far from being proved, of course, but clearly we must look for something of the sort if we are to understand how Nature has succeeded in erecting such a variety of structures on one foundation. There must be something comparatively simple underlying it all, something simple and comprehensive, and we suggest, on the basis of a long series of x-ray and related studies,⁶ that the truth does indeed lie in the direction indicated. Add to the single postulate just formulated the principle of close packing long recognized by crystallographers, and at least the broad characteristics of the group seem to follow inevitably. Similar remarks apply to the collagen group: the collagen fibers rest on another foundation, but again it must support the whole immense group.

To the molecular biologist the problem of muscle is one of almost unrivalled fascination. We see it now as an exercise in the properties of proteins, or more exactly, in the properties of one particular protein, myosin, which turns out to belong to the same molecular family as the hair protein, keratin. Keratin too has the power of contraction* once certain cross-linkages that help to differentiate it from myosin have been broken; and in fact all the principal x-ray and elastic properties of myosin find their counterparts in those of the epidermis and the supercontracting form of keratin. Unfortunately, x-rays show no new *regular* pattern for the state that is shorter than the α -form, but such changes as are observed are always similar, whether in keratin, isolated myosin or *living muscle*, and never do they correspond quantitatively to a simple disorientation of the α -form, but rather to a further folding of the polypeptide chains. It is hard to resist the conclusion that muscular contraction is only another example—an exquisitely controlled example, but still only an example—of the kind of thing that occurs during the β - α transformation, the thermal contraction of the collagen fibers, or the elastic retraction of elastin and stretched denatured proteins. It is a shortening by intramolecular rearrangement, and *it takes its place logically between the extended, or β -, proteins on one hand and the corpuscular proteins on the other*.⁷

The scheme of folding illustrated in Figure 3 provides as yet the merest sketch of a full interpretation of the activities of the keratin-myosin group, and nothing is easier than to question it on points of detail. Details, however, from the very nature of the case, are largely the responsibility of individual members of the group, and in any event will not be forthcoming till we have many more data at our disposal. For the present, if we invoke only the two principles of roughly equal proportions of polar and non-polar side-chains (the evidence for which will be given below) and the close packing of these in such a way that polar is drawn to polar and non-polar to non-polar, then already the outlook is wider and more promising than anything before. The contraction of muscle appears as a consequence of increased facilities for aggregation induced by comparatively simple reversible changes in the relative distribution of polar and non-polar side-chains, and the fact that myosin is not only the working elastic mechanism but also a principal enzyme (adenosine triphosphatase⁸) in the elastic cycle becomes at once intelligible. It must mean that among the polar side-chains are included specific reactive groupings that leave the main elastic properties substantially unchanged while increasing the ver-

* To avoid confusion with contraction from the β - to the α -form on release from stretching, we have given the name "supercontraction" to the power that may be developed in keratin of contracting below its unstretched length.

satility or sensitivity of the system in relation to a particular chemical environment. The possibility of such a compromise is implicit in the scheme here proposed.

The state of affairs inside the molecules of the corpuscular proteins is still only an extrapolation from what has been discovered about the fibrous proteins. We know that denaturation ultimately liberates peptide chains—sometimes spinnable, fiber-forming chains of great length, sometimes much shorter chains (see below)⁹; but in only one instance so far has anything interpretable been observed by x-rays of the actual process taking place. Single crystals of the seed globulin, excelsin (one of the proteins from which, when fully denatured, artificial fibers can be spun), were found to give in the same x-ray photographs not only diffraction spots corresponding to a rhombohedral lattice of corpuscular molecules of weight about 300,000, but also three superposed fiber patterns with the fiber axes parallel to the hexagonal *a*-axes and the side-chains almost parallel to the basal plane.^{9, 10} The crystals had partially degenerated into what Osborne called "excelsan," though outwardly and optically they appeared quite sound. Obviously in this case, to produce so little disturbance, the transition from corpuscular to fibrous must involve an almost negligible change: internally the corpuscular molecules must be for all practical purposes fibrous, and the probability is that they are built from chains running backward and forward parallel to the crystal axes along which the fibers make their appearance.

All the indications are that denaturation is often an easy, unobtrusive process of this kind, and it seems likely that the intramolecular folds in many corpuscular proteins, especially those like the seed globulins without any highly specialized function, are no more complicated than the following:^{9, 11}

in which the side-chains (the R-groups) stand out alternately above and below the plane of the folds. The principle is the same as that of the proposed α -folds shown in Figure 3, except that the α -folds are approximately square instead of being long loops. It will be noticed that each loop is in the β -configuration; the α -loop, in fact, is merely the shortest possible β -loop and there is no formal difference between the two configurations: both α - and β -keratin have the same density, 1.3 gm/cc, and so have all proteins, roughly speaking.¹²

A further elaboration would consist of loops formed not from extended chains, as just described, but from α -chains, again as illustrated in Figure 3. In any case we should expect the folding to take place, in general, in planes transverse to the side-chains, and the next step in the argument leads automatically to the idea of laminae with side-chains projecting from both faces. A laminar structure is indeed already surmised for a number of corpuscular molecules, the most familiar being that of egg albumin, which is believed, as an inference from x-ray and monolayer data,¹³ to comprise four superposed laminae. Possibly even in highly specific corpuscular proteins the bulk of the molecule is built on some such straightforward lines, with the more specialized part, or prosthetic group, as an added complication. It is to be feared that it will be a considerable time, particularly amid the demands of war, before x-rays are in a position to adjudicate on these points with authority. for they present a formidable problem in diffraction analysis. The most promising single crystal studies in progress at the moment are those on insulin¹⁴ and hemo-

globin,¹⁵ which are being prosecuted chiefly through the medium of Patterson projections. It may or may not be significant as a direct link with the keratin-myosin group that the Patterson-Harker section of wet zinc insulin parallel to (0001) at $z = 0$ is characterized by a hexagon of high and well-defined peaks at 5 Å, that is to say, at practically the distance at which the strong intramolecular pattern of the α -fibers repeats; but at least it will be granted that it is exceedingly stimulating and worthy of the closest investigation. We might expect *a priori* some system of close packing among the side-chains if it is at all possible, and the suggestion here is that the same system is used in insulin as in the keratin-myosin group. It is no more than a suggestion, however, and much work remains to be done before a decision is reached.

Questions of the folds or of almost any internal feature of the proteins are of course inseparable from that of chain length, but it is only recently that light of a clearer sort has been thrown on the latter. In the fibrous proteins, as a rule, it can hardly be doubted that the chains are of great length, and the same is true of the artificial fibrous proteins spun from denatured seed globulins; but for the majority of corpuscular proteins we have only such evidence as comes from ultracentrifuge¹⁶ and dissociation experiments, indicating that the greater molecules seem to be built up of lesser units, and therefore that a fair number of shorter chains instead of a few longer chains might be more usual than had hitherto been supposed. Some years ago, as part of an x-ray study of the fiber-forming properties of denatured proteins,⁹ the experiment was tried of stretching strips cut from films of "poached" egg-white; it was found very surprisingly that, whereas the chain-bundles in denatured seed globulins tended to set along the direction of stretching, those in denatured egg-white tended to set *across* the direction of stretching. There could be only one interpretation of this, that the chains in denatured egg-white are much shorter than in denatured seed globulins; and similarly for the native molecules, presumably. The observation fits in nicely with the inference, mentioned above, that the native egg albumin molecule (weight about 43,000) consists of four superposed laminae and therefore possibly of four more or less discrete chains, but it takes on a new interest and importance now that Chibnall's¹⁷ chemical analytical data point to the same number. Chibnall has shown, furthermore, that in edestin (a seed globulin) there can only be one chain per weight of 50,000. These results mean that the edestin chains are of the order of five times as long as the egg albumin chains, and the surprise engendered by the poached egg experiment, though innocent, was perhaps unmerited!

Chibnall's method has been to make exceptionally painstaking analytical determinations of the numbers of acidic and basic residues, and then to compare them with the data given by titration and Van Slyke's nitrous acid procedure: the discrepancies, if such exist, lead to an estimate of the numbers of free carboxyl and amino groups at the ends of chains. In this way he has shown, in addition to the results just quoted, that there are probably eighteen chains in the insulin molecule and nine in the lactoglobulin molecule. Below we shall consider the fundamental bearing these findings have on the central problem of protein stoichiometry—the problem of the laws governing the proportions and distribution of the residues—but in the meantime it is gratifying to note, as a further stimulating approach to the crystallographic solution of insulin, that Crowfoot's Patterson projection on (0001) also suggests a compounding of the molecule from eighteen sub-units. There is nothing yet to identify Chibnall's eighteen peptide chains with Crowfoot's eighteen sub-units, but again it will be granted that here is something very promising to work upon.^{14, 18} Riley¹⁹ has carried out a lengthy x-ray study of the crystal structure of lactoglobulin, and he too has found evidence of sub-units—not so clear nor in such direct correspondence to Chibnall's results as in the case of insulin, but still definitely hopeful.

Everything in protein studies turns ultimately on the numbers and distribution

of the amino-acid residues. Their weights range from that of glycine (57) to that of tryptophan (186), giving an arithmetic mean of about 120. Roughly then, 100 gm of protein should contain something of the order of $100/120 = 0.83$ gram-residue of amino-acids; and if the yield of any particular acid is large, it may be possible at once to hazard a sound guess as to what fraction of the total residues arises from that acid. For example, the leucines yield from hemoglobin has been reported^{20, 21} as 27.8 gm and 29.5 gm, corresponding to 0.21 — 0.22 gram-residue; and from insulin the leucines yield²² of 30 gm corresponds to about 0.23 gram-residue; so that in both these cases the suggestion is that one-quarter of the residues are leucine or isoleucine residues. Similarly, from gliadin, 43 gm of glutamic acid²³ corresponds to rather more than 0.29 gram-residue (all in the form of glutamine residue, to judge by the amide nitrogen), with the suggestion that one-third of the residues are glutamine residues; and again, from silk fibroin, the reported yields^{24, 25} of 40.5 gm and 43.8 gm of glycine, corresponding to 0.54 and 0.58 gram-residue respectively, indicate that as many as half the total residues in fibroin are glycine residues (since a high glycine content must give a low average residue weight). With single *low* yields we can of course feel no such confidence; nevertheless it has been observed for some time that certain yields, expressed as gram-residues, at least bear a simple numerical relation to one another, and that again, as with the examples just quoted, powers of 2 and 3, or products of such powers, seem to be common. Block²⁶ pointed out, for instance, that the hemoglobins from the horse, the sheep and the dog all contain iron, histidine, arginine and lysine in the ratio 1:8:3:9, and that in the keratins the ratio of histidine, arginine and lysine is about 1:15:5 (since modified²⁷ to 1:12:4); and Atkin²⁸ pointed out that Dakin's results indicate that glycine and hydroxyproline residues are present in gelatin in the ratio of 3:1; and so on. Other examples could be cited, but these will serve to illustrate a growing impression during the past ten years or so.

In 1933 the writer, with H. J. Woods, made the first attempt to link up the ratios of gram-residues with x-ray and physico-chemical data on wool keratin.²⁹ This was followed by the application of similar ideas to the problem of gelatin;³⁰ and on the basis of chemical analyses then available it was concluded that "the residues of the two chief acids, glycine and oxyproline (hydroxyproline), account, respectively, for about one-third and one-ninth of the total number of residues; that is to say, every third residue could be a glycine residue and every ninth an oxyproline residue."³¹ The way this conclusion was reached was as follows. The total nitrogen content of gelatin was reported as 18 per cent, and the reported yields of amino-acids corresponded to a nitrogen content of 15.64 per cent: the difference, 2.36 per cent, came from acids still unaccounted for, and these were very probably monoamino-monocarboxylic acids. The undetermined acids amounted therefore to $2.36/14 = 0.16$, gram-residue, which brought the 0.87, already reported up to 1.04 gram-residues. Now 1.04 is, within the limits of experimental error, three times the number of gram-residues of glycine (0.34) and nine times the number of gram-residues of hydroxyproline (0.11).

Since that time Bergmann and Niemann³² have proposed two fundamental principles that are generalizations of these early suggestions. They postulate that *all* proteins are built according to the following rules: (1) the numbers of the different kinds of residues and also the total numbers of residues in the molecule are always of the form $2^n 3^m$, where n and m are positive integers or zero; and (2) the residues of any one kind always occur at a regular periodic interval along the polypeptide chain or chains.

The most striking evidence for the validity of the $2^n 3^m$ rule under certain conditions has recently been obtained by Chibnall,¹⁷ working with edestin. Chibnall estimates the average residue weight (R) from a consideration of the nitrogen distribution, after the manner just described for gelatin:³¹ his value for edestin is 115.7, and

the number of gram-residues (G) in 100 gm of protein is $100/115.7 = 0.864$. Table 1 is a modified expression of Chibnall's results.¹⁸

Table 1. Edestin.

| | $R = 115.7$ | | $G = 0.864$ | | |
|---------------------------|-------------|---------------------|---------------------|--------------------|-----------------|
| Amino-acid | Yield (%) | Obs. | Gram-residues Calc. | Frequency * | |
| Histidine | 2.41 | 0.0156 | 0.0160 | 54 ($2^{13}3^2$) | |
| Arginine | 16.71 | 0.0961 | 0.0961 | 9 (3^2) | |
| Lysine | 2.37 | 0.0162 | 0.0160 | 54 ($2^{13}3^2$) | |
| Tyrosine ³³ | 4.34 | 0.0240 | 0.0240 | 36 (2^23^2) | |
| Tryptophan ³³ | 1.50 | 0.0073 ₅ | 0.0080 | 108 (2^23^3) | |
| Methionine ³³ | 2.35 | 0.0158 | 0.0160 | 54 ($2^{13}3^2$) | |
| Cystine/2 | 1.44 | 0.0120 | 0.0120 | 72 (2^33^2) | |
| { Glutamic acid | 20.7 | 0.1408 | 0.0720 | { | 12 (2^23^1) |
| { Glutamine | | | 0.0720 | | |

| { Asparagine | 12.0 | 0.0902 | 0.0540 | { | 16 (2^4) |
| { Aspartic acid | | | 0.0360 | | |
| L.C.M. = 432 (2^43^3) | | | | | |

* The "frequency" is simply the reciprocal of the fraction of the total residues, without prejudice to the question whether the residues of any one kind are equally spaced along the chain or chains.

The agreement shown in Table 1 is so excellent that there can be no doubt now that for edestin at least, for the amino-acids quoted, the 2^n3^m rule holds strictly. The position with regard to the other amino-acids must remain open pending further exact analyses, but in the meantime it is clear that there are no fewer than 432 (2^43^3) residues in the molecule, and therefore the molecular weight must be $432 \times 115.7 = 50,000$ approximately, or a multiple thereof. The multiplying factor is presumably 6, since the ultracentrifuge¹⁸ gives a molecular weight of 310,000.

Chibnall's equally careful results for egg albumin and lactoglobulin, on the other hand, give no such unequivocal support for the $2^3 3^m$ rule. They are given in Table 2. The discrepancies are still no proof, however, that the structures of these two proteins do not rest fundamentally on a $2^3 3^m$ basis, because on the one hand recrystallized egg albumin has been shown by electrophoresis to contain two components³⁶ and each component contains probably four chains,¹⁷ and on the other, lactoglobulin, though homogeneous, probably contains nine chains per molecule.¹⁷ Each component or chain, as the case may be, could conform separately to the $2^3 3^m$ rule, but groups of components or chains need not so conform: to what extent agreement is found in group analyses must depend on the number and kinds of dissimilar components.

The literature of protein analysis reveals many exact agreements, approximate agreements, and seemingly flat contradictions like those just quoted.¹⁸ Data such as Chibnall's on edestin, egg albumin and lactoglobulin are just the sort of thing needed to make sense of the accumulating concordances and discrepancies; for undoubtedly there are enough of the former to demonstrate the existence of a $2^3 3^m$ rule of some kind or other, yet quite enough of the latter also to show that it cannot be of general validity in the form in which it was first expressed. In the light of what we know now, the most reasonable point of view would appear to be that the rule holds at least for structural sub-units, and hence sometimes partially, sometimes completely for structures as a whole, according to the number and kinds of dissimilar sub-units. The fact that it holds so extensively—perhaps absolutely—for edestin is thus a stoichiometric indication that the edestin molecule should consist of only a few long chains, and this is confirmed not only by the pronounced fiber-forming properties and x-ray photographs of the denatured seed globulins⁹ but also by Chibnall's estimate of the chain-length.¹⁷ Similarly, from Table 2, we might expect egg albumin to consist of a number of shorter chains, and this again is confirmed both by x-rays and by Chibnall's findings. Experiments are now in progress to try to extend the x-ray method to other corpuscular proteins.

Table 3. Comparative Chemical Constitutions of Wool Keratin and Rabbit Myosin for the More Reliable Amino-acids.

The stoichiometry of the fibrous proteins, though no doubt amenable ultimately to some form of the $2^3 3^m$ rule, must rest also on a wider basis, as already pointed out

Table 3¹⁸ shows the range of variation in chemical constitution between wool keratin and rabbit myosin for the more reliably determined amino-acids. There are good grounds for believing that what is aimed at with regard to the acidic and amide residues is that keratin and myosin shall have the same numbers of asparagine and glutamine residues (24 and 32, respectively), while myosin shall have twice as many of both aspartic and glutamic acid residues (24 and 64) as keratin has (12 and 32);

FIGURE 4a. Stretched foot retractor muscle of *Mytilus edulis* showing partial transformation into β -myosin.

FIGURE 4b. Living relaxed foot retractor muscle of *Mytilus edulis*.

but otherwise there seems to be no obvious correlation between the two sets of data, beyond the fact that the polar residues amount in each case to practically half the total (neglecting cysteine residues, of which in myosin there are about 2 in 576, the polar residues add up to 273 in keratin and 284 in myosin). The situation recalls mixed crystallization and alloy formation, in which it is the crystallographic *sites* that are significant, rather than the specific atoms or groups that occupy them; and we get the impression that what counts in the keratin-myosin series is that certain sites within the structure shall be occupied by certain *types* of residues. Figure 5 is an example of what is meant:^{5, 18} it postulates three main types of polar cross-linkage, acid-base, amide-hydroxyl and hydroxyl-hydroxyl, and it adapts, within the framework of Figure 3, the well-established concept of "ideal" or limiting structures, one at either end of the series. Of the polar cross-linkages in the limiting keratin, one-third are salt linkages, one-third amide-hydroxyl bridges, and one-third hydroxyl-hydroxyl bridges; while in the limiting myosin (from which rabbit myosin itself is not far removed), two-thirds are salt linkages and one-third amide-hydroxyl bridges. The experimental evidence suggesting such a scheme lies in the following analytical figures,^{5, 18} the "ideal" limiting figures being shown in brackets for comparison:—

| | Basic | Type of residue (Nos. in 576) | | Hydroxyl |
|--------------------|---------|-------------------------------|---------|-----------|
| | | Acidic | Amide | |
| Wool keratin..... | 55 (48) | 44 (48) | 55 (48) | 119 (144) |
| Rabbit myosin..... | 81 (96) | 89 (96) | 57 (48) | 57 (48) |

Another way of realizing the interchangeability of residues that runs through the keratin-myosin series could be by means of a variable grouping-together of chains or grids of constant composition, with each chain or grid perhaps conforming strictly to the 2ⁿ3^m rule. On the whole, bearing in mind the multiple-chain structure of egg albumin, insulin and lactoglobulin, the evidence is possibly more in favour of this

FIGURE 5. Proposed plan for the packing and cross-linkage of polar side-chains in the keratin-myosin series.

FIGURE 6. X-ray fiber photograph of the tip end of a porcupine quill, dried in vacuum over phosphorus pentoxide. Cu $K\alpha$ rays. Specimen-to-film distance = 9.7 cm. Collimator 13×0.025 cm (MacArthur).

solution than the one just outlined, though it is quite reasonable, for all we know to the contrary, to suppose that both methods are used according to circumstances. An important crystallographic fact with regard to the fibrous proteins that may well find its true explanation in terms of this second solution is the occurrence in their x-ray photographs of large side-spacings, which show that the structural units must be composed of a number of different, or differently oriented, chains lying side by side. This strongly reminds us of the plagioclase feldspars, built from continuously varying proportions of albite ($\text{NaAlSi}_3\text{O}_8$) and anorthite ($\text{CaAl}_2\text{Si}_2\text{O}_8$), and the recent x-ray interpretation of their structure as a system of fine lamellae.³⁷

At the moment, the final elucidation of the structure of the keratin-myosin group looks most promising by way of porcupine quill, which gives much the best x-ray diffraction patterns of the series. Figure 6, due to MacArthur,³⁸ is a reproduction of the central region of the porcupine quill photograph: the prominent group of reflections near the top and bottom corresponds to the arcs—the only arcs—seen in Figure 1b. Figure 7, also due to MacArthur, is a composite diagram that includes most of the α -keratin pattern as we know it now.

The molecular pattern along the fiber axis of porcupine quill repeats at probably 658 Å, and the strong meridian reflection of spacing 5.14 Å that is so characteristic of the keratin-myosin group is the 128th (2^7 th) order of that period. If 5.14 Å represents the length of an intramolecular fold comprising three residues, as we believe, then a single chain of the pattern-length revealed by x-rays would contain 384 ($2^7 \cdot 3$) residues, or a multiple thereof. Chemical analysis indicates 576 ($2^6 \cdot 3^2$) residues,^{5, 18} but there is not necessarily any conflict, because both the x-ray and the chemical analytical numbers quoted must be considered for the present only as the smallest compatible with the experimental data, and because the chain may conceivably be folded into long loops—it is easy, in fact, to suggest a type of loop that would conform with both numbers. The important thing to notice is that 384 is of the form $2^n 3^m$, and, what is more impressive still, that *almost all the dominant reflections along the fiber axis are orders of 658 Å that are exactly or nearly of the form $2^n 3^m$.*

Chemical analytical data for porcupine quill are still impossibly scanty, so there is no opportunity yet of trying to link up this pregnant discovery with the residue frequencies. In wool keratin,^{5, 18} however, these frequencies are mostly quite close to numbers of the form $2^n 3^m$, and without doubt they will be found to be so in porcupine quill too. It follows from the porcupine quill diffraction pattern that such chemical relationships can no longer be thought of as amusing coincidences arising out of a combination of experimental errors and wishful thinking. The structural stage is now set for the third act.

Outside the keratin-myosin group almost all other natural protein fibers—all such things as the white connective tissue fibers, tendons, cartilage, the scales and fins of fishes, the ichthyocol of swim-bladders, jelly-fish and many other structures²—fall into the collagen group, for they all give diffraction patterns of the type shown in Figure 1e. The pattern is not in every case identical, it must again be emphasized, but all the photographs share certain features that point to a common molecular plan conserved in spite of variations in chemical constitution, just as in the keratin-myosin group. Unfortunately, very few good chemical analyses are available for pure collagen fibers, most analyses having been carried out on gelatin, the protein derived from collagenous structures by breakdown of a hydrolytic nature. Oriented gelatin, however, still gives the typical main outlines of the fiber pattern, and it is permissible to make use of gelatin analyses in at least a preliminary skeleton interpretation.

The collagen problem has been discussed at length elsewhere,^{2, 18} and the barest summary of things must suffice here. The fibers are normally not elastic in the sense of the keratin-myosin fibers, and stretching them does not alter the x-ray

FIGURE 7. Composite diagram of the α -keratin diffraction pattern given by porcupine quill (Cu K α rays). The spacing of the most prominent arc on the meridian is 5.14, Å (MacArthur).

photograph except for orientation effects; but they contract spontaneously at temperatures above about 60-70° C and then show long-range elasticity from their shortened length. Everything points to the polypeptide chains being normally in some configuration that is stereochemically fully extended—a configuration that is folded up irregularly when the temperature is raised high enough in the presence of water, or even without raising the temperature in the presence of certain swelling agents—yet the diffraction pattern seems to demand chains that are considerably shorter than fully extended; in fact, it suggests an average residue length about equal to the spacing (2.86 Å) of the strong meridian arc that is so characteristic of the group.

To resolve this conflict of evidence it is inevitable to look for peculiarities in the chemical analytical data, and there indeed the most reasonable answer lies. The solution is once more one of stoichiometry, a question of the proportions of the amino-acid residues, or more precisely, of certain kinds of residues.

Table 4.¹⁸ Gelatin.

* For collagen also.

Table 4 collects various determinations made on the more abundant amino-acids in gelatin (with two results for collagen proper): they account for some six-sevenths of the total. One-third and one-ninth, as mentioned earlier in this article, must be allotted to glycine and hydroxyproline, respectively; but now we know too that about one-sixth must go to proline. Thus nearly one-third (actually $\frac{5}{18}$) of all the residues are *imino* residues, which in itself is sufficient to diminish the average residue length without invoking intramolecular folds. When a model is constructed, the decrease is found to be just about what is required, and the most probable configuration is of the form:

This is no more than the general scheme, it should be remembered, on which many variations are possible and are doubtless realized in nature: one way, for example, must be by virtue of the fact that once in every 18 residues or so the imino ring is lacking, and the gaps are available for a variety of other residues. We have to explain the occurrence of a great family of structures of differing chemical constitution but built to a common plan; and just as in the keratin-myosin group a single master key may be found in an alternation of polar and non-polar residues, so in the collagen group the key seems to lie in the proportions and preponderance of glycine and imino residues.

The full repeat of molecular pattern along the fiber axis in collagen is of great length. It had been inferred for some time² that it was a multiple of approximately $209\frac{1}{2}$ Å, but quite recently Bear,⁴⁶ working with dried beef tendon, has recorded ten of the innermost orders of a fundamental period that he estimates to be about 640 Å. The overall average from Bear's data and those of other workers is about 636 Å, which on the interpretation favored here is equivalent to the length of something like 216 (2³3³) residues.

This article could hardly close better than with a reminder of what was said in the opening paragraph; but in spite of the confessed inadequacy of the present discussion it is to be hoped that one point at least has been made clear; that far-reaching developments are maturing. The story of the proteins is as long and involved as any with which the human mind has grappled, but never was there a more worthy theme, and surely now a crisis is near.

Catalysis As a Biological Factor

JEROME ALEXANDER

Introduction

The complex and multiform phenomena of life and living units (bionts) confront us with two apparently incongruous and irreconcilable facts. Most notable is the tendency of bionts to breed true. Regardless of wide differences in food and surrounding conditions, the fundamental processes of life appear, as a rule, to be unerringly shepherded along definite paths and sequences; so that despite the vagaries of wind and wave the ship of life maintains a fixed course. Closer study, however, reveals the opposing fact that the course of life, whether of the individual or of the mass, never does run smooth. We have ample evidence of disease, abnormalities, and idiosyncrasies, of mutation and evolution, no matter how we may differ in our attempts to explain these deviations from ideal normality.

Catalysis, involving the direction of definite chemical changes by surfaces of definite structure under definite conditions, seems to be the only basic principle at present known which can mainly account for both the normalities of life and the many deviations from normality. This does *not*, of course, mean that no other factors or principles are operative, especially in relatively large and complex organisms and at structural levels lower and higher than the molecular. But in final analysis it will be seen that these other factors influence the functioning of the biocatalysts—genic, enzymic, structural or symbiotic—which dominate the chemical changes whereby life exists, persists, and proceeds.

If biocatalysts and the conditions of catalysis remained unchanged, we would not expect any change in the biochemical output, which underlies all larger structure, morphology, and function. Where we find a change in the biochemical output under apparently unchanged conditions, we are strongly justified in suspecting that some catalyst or catalyst system has undergone an intermolecular or interparticulate readjustment, that something has been added to or subtracted from active catalyst areas, or that new catalyst areas have been formed. These catalyst changes recall the well-known commercial practices used in preparing very active and specific catalysts, which aim not only to keep harmful substances from the catalyst surface, but also to insert there very small amounts of substances termed "promoters," because they direct or favor the formation of desired end products.

It is believed that a very wide range of biochemical and biological phenomena become easily understandable on the basis of specific catalysts and specific catalyst formation and/or changes; and also that no other simple, basic, and ubiquitous phenomenon is equally consonant with the experimental evidence over so wide a range.

Catalysis in General

Time is of the essence of all biological happenings. It is, therefore, purely academic whether, (as many texts put it), catalysts simply speed up reactions which would occur over the lapse of indefinite time, or whether (as seems more probable) catalysts initiate, in many cases, at least, reactions which would not otherwise occur.

A relatively tiny quantity of catalyst may determine the building up or breaking

down of enormous numbers of molecules. The "key" of a "zipper" fastener, commonly used on bags, tobacco pouches, sweaters, dresses, and other articles of clothing, has some analogies to a catalyst.^{6a} Drawn in one direction, it massages the opposing "hooks" of the closure so that they engage each other and hold firmly; on reversing the motion of the "key," the opposing "hooks" are disengaged and the closure opens. As far back as 1898, Croft Hill³⁷ showed that the action of catalysts may be reversible. Using a biocatalyst, the yeast enzyme maltase, he built up from glucose what was first thought to be maltose, a disaccharide, but what was later shown to be isomaltose.

The analogy between "key" and catalyst may be carried a bit further. Recalling the dictum of Emil Fischer⁵⁶ that enzyme and substrate must be adjusted to each other like lock and key, we see that there is a mechanical specificity between any zipper key and the hooks that it can influence. At temperatures approaching the softening point of the metal of which the key and the hooks are formed, we would expect the opening and closing processes to fail. Prolonged use might wear down the key so that it would no longer function; or a deformation of the key or the hooks, an adhering drop of paint or solder, or a bit of wire might bind the key fast. Similarly catalysts are highly specific in their action, and they may be utterly ruined, or temporarily or permanently obstructed, masked, or "poisoned."

How Catalysts Function

The view that catalysts function by virtue of their externally directed electronic fields of force becomes clearer when we consider recent revelations of molecular electronic contour by the x-ray spectrometer. Figure 1 shows what may be termed a surveyor's map of a molecule of nickel phthalocyanine, and Figure 2 shows an electronic surface contour map of the same molecule, foreshortened because it is set at an angle in its crystal. Compare this with Figure 3, showing a similar map for phthalocyanine itself, and note the changes in electronic contour about the center of the molecule, brought about by the introduction of a single nickel atom. The importance of such a single atom is indicated by the fact that A. H. Cook³⁶ found that iron phthalocyanine, alone of the metallic phthalocyanine derivatives tried, possesses marked catalase properties (catalysing the decomposition of hydrogen peroxide). This is especially interesting because of the similarity of the structure of phthalocyanine to that of porphyrin, a constituent of hemoglobin, of chlorophyll, and of cytochrome and other enzymes.

If instead of a single molecule we consider a small group * of molecules, the complications of structure are much greater. Figure 4 shows a number of naphthalene molecules assembled as they are in a single surface cleavage layer of a naphthalene crystal, and Figure 5 shows the type of electronic surface presented if a naphthalene crystal is cut across.

Berzelius,²¹ who coined the word *catalysis*, keenly anticipated the modern view that catalysis is consequent upon distortion of reactants by the electronic fields of the catalyst, for he said:

"It is then proved that several simple and compound bodies, soluble and insoluble, have the property of exercising on other bodies an action very different from chemical affinity. By means of this action they produce, in these bodies, decompositions of these elements and different recombinations of these same elements to which they themselves remain indifferent.

"This new force, which was hitherto unknown, is common to organic and inorganic nature. I do not believe that it is a force quite independent of the electrochemical affinities of matter; I believe, on the contrary, that it is only a new manifestation of them; but, since we cannot see their connection, and mutual dependence, it will be

* The group may be small, though the number of molecules may run into the hundreds or thousands.

more convenient to designate the force by a separate name. I will therefore call this force the catalytic force, and I will call catalysis the decomposition of bodies by this force, in the same way that one calls by the name analysis the decomposition of bodies by chemical affinity."

As the electronic patterns of catalysts are more or less thermolabile, temperature

FIGURE 1. Dimensions of the Nickel Phthalocyanine Molecule (Robertson).

is an important factor in catalysis. What we measure as the "temperature" of any system represents an integration of the kinetic activity of its particles over an interval of time long enough to affect a measuring instrument (thermometer, thermopile). During this interval, individual atomic or molecular units of the system will undergo wide variations in their internal electronic configurations and therefore in their outwardly directed fields of force; and individual particulate kinetic units will vary widely in their rotation and free path motion from one instant to another. This raises the question as to whether any *individual* particle has a *measurable* temperature, or, indeed, any lasting temperature at all. Various kinds of radiation (light, ultraviolet, infrared, x-rays) may produce an effective activation of atoms or of molecules without any determinable increase in temperature, although some of the atoms or molecules would be momentarily brought into a state of "excitation" constituting a prelude to chemical change.

After completion of a catalytic change a statistical chemical analysis gives us the final results, but an understanding of the mechanism whereby the results were reached will often aid in controlling or modifying them.²

In his monograph on mechanisms of biological oxidations, David H. Green states (p. 9):⁶⁰ "The next problem is to explain how the substrate undergoes oxidation when combined with the enzyme. On that point experiment is silent though theory is eloquent. It is stated that the enzyme 'activates' the substrate or that a 'strain' is

FIGURE 2. Projection of Nickel Phthalocyanine Along the b Axis, which makes an Angle of 44.2° with the Molecular Plane. (J. M. Robertson.) Each contour line represents a density increment of one electron per \AA^2 , except the nickel atom where the increment is five electrons per \AA^2 for each line. The one-electron line is dotted.

imposed on the substrate molecule. These are terms of ignorance and merely express the experimental fact that the substrate undergoes an oxidation in presence of the enzyme which it does not undergo spontaneously. The nature of activation or straining of the substrate molecule is the spearhead of present research in biological oxidations."

However, when we envision the activation of a substrate as due to a specific strain exerted upon its specific electronic areas by the specific electronic areas of the

FIGURE 3. Projection of Phthalocyanine along the b Axis (J. M. Robertson).

FIGURE 4. Projection of Naphthalene Molecules Along the b Axis, showing Mutual Relation of Molecules. Each Line Represents One Electron per \AA^2 (J. M. Robertson.)

catalyst, we begin to approximate the "screw and nut" analogy of Pasteur and the "lock and key" analogy of Emil Fischer, and do somewhat more than merely express the experimental fact. We see open before us a simple physico-chemical principle, closely dependent on chemical structure and therefore indefinitely variable, which presents, nevertheless, a readily comprehensible mechanism for understanding both the mode of functioning and the extreme specificity of enzymes and other catalysts. Naturally, we are then confronted with the enigmas of electronic contours, which physicists can measure and delineate in some cases. Referring to the violent evolution of O_2 when H_2O_2 is added to a strong catalase solution, Green says (p. 17): "The available evidence indicates that the excessively short life period of the complex [between the substrate and the enzyme] explains why addition of H_2O_2 does

FIGURE 5. Projection of Naphthalene Along the c Axis. Each Contour Line Represents two Electrons per \AA^2 (J. M. Robertson.)

not affect the [spectral] absorption bands of catalase." But these bands are greatly changed by substances that are fixed by the catalase, *e.g.*, KCN, NaF, H_2S . Whether the catalase- H_2O_2 complex is to be considered a "chemical compound" or not will depend upon our definition of this expression. But the taxonomic tag will not change the physical fact.

The Industrial Importance of Catalysis *

A constantly increasing percentage of the annual output of sulphuric acid, a basic raw material of chemical industry, is being produced by passing a mixture of air and sulphur dioxide over vanadium or platinum catalysts.† The chamber process, which for so many years dominated the field, may soon survive mainly in textbooks.

At the Eighth International Congress of Applied Chemistry (New York, 1912). German chemists announced the perfection of the Haber process, whereby hydrogen and nitrogen are catalytically combined to form ammonia gas, which can be catalytically oxidized to nitric acid. Germany was thereby rendered independent of importations of sodium nitrate (Chile saltpeter) for explosives, agriculture, dyes, etc. and she began the long-planned war in 1914, as soon as the new Haber plants were in full operation. To illustrate how large an amount of chemical change may be

* See "Catalysis, Inorganic and Organic," by Sophia Berkman, Jacques Morrell & Gustav Egloff. Reinhold Pub. Co., New York, 1940. In 1941 about 60 million gallons of methanol were made catalytically in U. S. A.

† Apart from lower cost, vanadium catalysts have the advantage over platinum of not being "poisoned" by arsenic, a common impurity in the sources of sulphur dioxide.

effected by a small amount of catalyst, it is said that $1\frac{1}{2}$ to 2 ounces of platinum distributed on silica gel can produce daily one ton of 100 per cent sulphuric acid, and that under optimum conditions one ounce of 10 per cent rhodium-platinum will catalyze the formation of over one million pounds of nitric acid.

In the organic field, enormous tonnages of petroleum, natural gases, and by-product gases from cracking petroleum are treated catalytically to produce a great variety of organic chemicals, many of which, even if known, had never before been produced in commercial quantities. Because of an abundant supply of coal tar in Europe, technical organic chemistry there revolved largely about aromatic substances derivable from benzene, phenol, naphthalene, anthracene, etc. The abundance of natural gas and petroleum in America beckoned our newly developing organic chemical industry into the aliphatic field, where extensive use is made of catalysis. Formaldehyde is made by the catalytic oxidation of methane as well as of methanol; and methanol may be synthesized by passing carbon monoxide and hydrogen over chromium and manganese oxide catalysts.* Large tonnages of unsaturated fats and oils are hardened by hydrogenation with the aid of nickel catalysts.

The chemical nature of the catalyst may determine the course of chemical change. To take an extremely simple case, the facts with formic acid are as follows:

- (1) Pd, Pt, Cr, Ni, Cd, and the oxides of zinc and tin catalyze the following type of breakdown:

With Pd and Pt sponges total decomposition occurs at 245° and at 215° respectively.

- (2) TiO_2 and the blue oxide of tungsten give a different result:

- (3) SiO_2 , ZrO , and uranous oxide catalyze the decomposition thus:

Thoria can catalyze any of these three types of decomposition, depending on temperature.

Catalyst Carriers, Poisons, Promoters, and Modifiers

The technological and patent literature has long reflected the fact that the introduction of new atoms or molecules into the active surface of a catalyst may stimulate, inhibit, or alter the nature and/or rate of the catalyzed reaction.⁷⁶ If a desired result is accelerated, the added substance (as mentioned above) is termed a promoter; if it is inhibited, the added substance is called an inhibitor or poison. In cases where a catalyst can direct the formation of several substances and an inhibitor is found which depresses undesired reactions, we speak of "beneficial poisoning." In a general sense any substance which changes the behavior of a catalyst may be called a modifier, a term free from implication as to the result of the change. The importance of *catalyst modification* in biology will be referred to later on.

One factor in the efficiency of a catalyst is the amount of free active surface it exposes to the reactants. It is common commercial practice to distribute the catalyst substance on carriers, or supports, such as asbestos, charcoal, alumina, diatomaceous earth (kieselguhr), etc., which were supposed to act merely mechanically. It has been found, however, that the carrier often exercises a marked effect, either by contributing small amounts of impurities to the catalyst surface (which may thus be either promoted or poisoned), or else by forming with the catalyst molecules some new composite surface of different activity.

To illustrate the importance of the carrier, it may be mentioned that Adkins, Richards and Davis³ found marked carrier effects in the catalytic dehydrogenation of hydromatic compounds containing a completely or partially saturated benzene,

* Other catalysts are also used commercially.

naphthalene or phenanthracene nucleus. In the case of decahydronaphthalene, the yields of naphthalene varied not only with the catalyst but also with the carrier.

| Catalyst | % yield of naphthalene from deca hydronaphthalene |
|---------------------------|--|
| Pt on charcoal..... | 87 |
| Ni on charcoal..... | 34 |
| Ni on chromium oxide..... | 78 |
| Ni on kieselguhr..... | 62 |
| Ni on Alumina I..... | 0 |
| Ni on Alumina II..... | 11 |
| Ni on Alumina III..... | 0 |
| Ni on Alumina IV..... | 36 |

Note: The charcoal was purified Norit. Alumina I was prepared through sodium aluminate; alumina II, III, and IV, by hydrolyzing alumina isopropoxide by three different procedures.

The authors remark that nickel on alumina and on kieselguhr are better catalysts for the dehydrogenation of substituted cyclohexanols than is platinum, because they show less tendency to induce condensations. Nickel on chromium was the most active catalyst in the case of resistant saturated hydrocarbons. In all, 28 representative compounds, including hydrocarbon alcohols, ketones, and ethers, were heated at 300° to 350° in the liquid phase under nitrogen, in the presence of the catalyst and also of benzene, which serves as a hydrogen acceptor or oxidizing agent.

The potent effect of catalyst poisons is brought out by the remarks of H. Bernthsen at the Eighth International Congress of Applied Chemistry (1912) relative to the iron catalyst used in the first step of the Haber process:

"Extremely minute quantities of these bodies (impurities), which are almost always present even in the purest commercial products or in so-called pure gases, suffice to render the catalysts absolutely inactive or at least to diminish their activity very seriously. Thus iron, for example, prepared from ordinary iron oxide with a content of one per thousand of sodium sulphate is, as a rule, inactive. Iron containing 0.1 per cent sulphur is generally quite useless, and even with 0.01 per cent is of very little use, although in appearance and when examined with the ordinary physical and chemical methods no difference at all can be detected as compared with pure iron.

"The recognition of these facts gave rise to two problems: (A) The preparation of contact masses free from poisons or the removal of poisons from them; and (B) freeing the gases to be acted upon catalytically from all contact poisons. A trace of sulphur, one part per million, in the gas mixture, can under certain conditions be injurious, so that electrolytically prepared hydrogen must generally be further specially purified."

Since a small amount of a catalyst may, if given sufficient time, direct an enormous amount of chemical change, we can understand how minute may be the quantity of promotor or modifier needed to produce a great change in the final output.

Experimenting with the catalytic production of methanol from carbon monoxide and hydrogen, Sir G. T. Morgan⁹⁶ observed that while catalysts made by calcining equimolecular mixtures of manganese and chromium nitrates gave methanol containing only traces of higher alcohols, catalysts prepared by precipitating a mixed solution of oxides of manganese and chromium in caustic potash gave a product containing appreciable percentages of higher alcohols. This led him to try the effect of regulated additions of alkali metals to the catalyst. To quote one outstanding case, when the catalyst contained 15 per cent of rubidium hydroxide, the carbon in the gases passing over the catalyst was distributed as follows: (with equimolecular proportions of the pure Mn and Cr oxides the yield of methanol was 80.5 per cent)

| | |
|----------------------------------|-------|
| Methanol..... | 41.5% |
| Ethanol..... | 1.6 |
| Higher alcohols..... | 36.7 |
| Aldehydes, acetals, ketones..... | 15.5 |
| Methane..... | 2.0 |
| Carbon dioxide..... | 2.0 |

The higher alcohols in this case consisted chiefly of isobutanol, but contained besides normal propanol, 2-methylbutanol, 2-methylpentanol, and 2, 4-dimethylpentanol.

Morgan found that the addition of cobalt to the catalyst gave mainly straight-chain alcohols, rather than the branching-chain alcohols formed by alkalized catalysts. This is shown by the following table which gives in *parts per thousand*, the alcoholic content of the *liquid* formed by passing the same mixture of carbon monoxide and hydrogen over different catalysts, under like conditions of temperature and pressure.

| Alcohols Formed | Catalyst Used | | | | |
|---------------------------|---------------|-----|------------|-----|----------|
| | Rb-Cr-Mn | | Co-Mn-Zn-K | | Co-Cu-Mn |
| Methyl..... | 420 | — | 198 | — | 220 |
| Ethyl..... | 12 | — | 86 | — | 200 |
| <i>n</i> -Propyl..... | 43 | — | 17 | — | 50 |
| <i>iso</i> -Butyl..... | — | 69 | — | 11 | — |
| <i>n</i> -Butyl..... | — | — | 4 | — | 16 |
| β -Methylbutyl..... | — | 8 | — | 1.5 | — |
| <i>n</i> -Amyl..... | — | — | 1 | — | 6 |
| β -Methylamyl..... | — | 6.5 | — | — | — |
| <i>n</i> -Hexyl..... | — | — | — | — | 2 |
| <i>n</i> -Heptyl..... | — | — | — | — | 1 |
| Unidentified..... | 89 | — | 1.5 | — | — |

In concluding his address before the Société Chimique de Belgique⁹⁷ Morgan said:

"All these experiments are of special significance, for they permit us to see the enormous variety of organic compounds which can be synthesized by secondary reactions following primary condensation of carbon monoxide and hydrogen, a gaseous mixture well known under the name of 'water gas,' made on a large scale from coal and steam.

"Up to the present time these condensations have been studied at temperatures higher than the decomposition of many organic compounds. With higher pressures and more efficient catalysts, we may some day expect to lower the reaction temperature very materially. When we shall have reached this point, the synthesis of organic compounds of great complexity should be possible and among these products we will find organic substances which up to now can be formed only by the chemical activity of living beings."

Some Kinetic Aspects of Catalysis; Zone of Maximum Colloidalilty

The catalysts used in industry are sometimes aggregated colloids (*e.g.*, platinum sponge, nickel used in hydrogenation); but generally they are extended on carriers. This not only exposes a large active surface, but it also permits the finely divided catalyst to remain in place when gases or liquids are passed over it, and to be filtered off if it has been mixed into a batch.

Some biocatalysts are fixed, like genes in the chromosomes; but most of the enzymes, which, with the genes, mainly direct the course of chemical change in bionts, are free particulate units of colloidal dimensions. The establishment of colloidal dimensions may come about in several ways. Some molecules are born col-

loids; some achieve colloidity by molecular growth or aggregation; and some have colloidity thrust upon them by adsorption or chemical fixation on a colloidal carrier or an extended surface.

Whatever the underlying cause, increase in particle size results in decrease in mean kinetic free path motion, as may be readily seen in an ultramicroscope. Particles at the lower ranges of microscopic resolution (about 0.25 micron) show only the feeble Brownian movement. On the other hand the kinetic motion of small molecules is so rapid that if we could see a hydrogen molecule we could not see it, any more than we can see a rifle bullet in flight. Between these two extremes lie all degrees of particulate kinetic motion, which increases at an accelerated rate as molecular dimensions are approached.

FIGURE 6. Degree of Colloidity Related to Particle Size.

But decrease in particle size is accompanied by great increase in specific surface—the amount of surface exposed per unit weight. That degree of dispersion where specific surface may exert its most effective influence before rapidly increasing kinetic activity dominates has been termed the zone of maximum or optimum colloidity.⁶ Figure 6 gives a *diagrammatic* sketch of these relationships, based on the *assumption* that the particles are spheres, which, of course, is seldom the case. Particles have various, and even varying contours (threads, rods, plates, aggregates), so that the diagram simply illustrates the principle.

When a particle approaches an active catalyst area, two factors are of outstanding importance:

- (1) the momentary electronic contours of the surfaces in apposition, for this determines the *possibility* of particulate union or influence;
- (2) the particulate kinetic velocities of translation and rotation of moveable areas, which determine whether the possibility may become a *reality*.

The importance of this kinetic factor came to the fore in the course of a lecture experiment * made at the Toronto meeting of the British Association for the Advancement of Science (1924) by Sir Ernest Rutherford, and was designed to illustrate how a positively charged atomic nucleus will repel an alpha particle emitted by radium. An electromagnet, with its positive pole up, was fastened to a table so that another electromagnet, swinging from the ceiling with its positive pole down, could just pass over it. The mutual repulsion of like magnetic poles caused the swinging magnet to take a parabolic path in any *off-center* approach. To illustrate the relatively rare recoil which occurs when an alpha particle makes a *direct* approach to an atomic nucleus, Sir Ernest took careful aim—but the swinging magnet passed completely over and beyond the fixed one, probably giving a slight unseen “jump” as it did so. Quickly retrieving the swinging magnet, he swung it again from a lesser distance and got the expected recoil.

From this it is evident that if a certain relative critical velocity is exceeded, particles or surfaces having the power to cohere, will *not* do so. In catalysis, a certain period of *time* is necessary for the electronic fields of the reactants to become fitted to each other, so that apart from the effects of particulate rotation, internal kinetics, and mode of presentation, the particulate kinetic velocity of translation is an important factor.

Increase in thermal agitation increases the *total number* of encounters *per unit of time* between reactant catalyst and substrate areas, and this works in favor of increasing the number of *fruitful* encounters. On continuing to increase the temperature, however, a point is reached where so many particulate units have so high a relative velocity, that the number of *unfruitful* encounters increases to such an extent that the catalyst efficiency per unit of time *tends* to fall off. Many other intercurrent factors may influence the thermal optimum in catalysis besides the kinetic factors; *e.g.*, the catalyst, reactants, or end products may undergo decomposition; adsorbed substances may “lame” the catalyst; specific substances or ions may affect the degree of dispersion or electronic integrity of catalyst or reactants. Thus Svedberg found that many proteins are dispersed into smaller sub-units by change in pH, some of them being reconstituted from the fragments when the pH is shifted to the stability zone; and many substances will “dissolve” or disperse glue at room temperature, *e.g.*, calcium chloride, sodium nitrate, sodium naphthalene sulphonate. The union of carrier and prosthetic group in enzymes is often delicately balanced (see below).

Pepsin is “activated” by hydrochloric acid. What this means kinetically may in part be followed ultramicroscopically.¹² A dilute solution of egg white heated nearly to boiling gave an opalescent dispersion full of bright, rapidly moving ultramicros. On allowing a droplet of pepsin solution (Fairchild's, containing 15 per cent alcohol) to diffuse under the cover glass of the slide, the albumin ultramicros immediately coagulated into large, motionless masses. When a droplet of 0.1*N* hydrochloric acid was introduced under the cover glass the coagulated masses burst into small groups and isolated ultramicros, which resumed their active kinetic dance. But almost immediately the albumin particles began to grow fainter and to disappear, the field meanwhile becoming brighter as smaller ultramicros or amicros were formed. The addition of pepsin to the opalescent albumin solution caused it to clear gradually at room temperature.

The kinetic motion of diastase particles may likewise be followed ultramicroscopically, as they gather about and actively rub or “gnaw” holes or cavities in starch granules.¹² The chemical changes occurring are, of course, far below the level of visibility.

Recently, Haurowitz and Schwerin⁶⁷ found that the catalytic auto-oxidation of linoleic acid by hemin in *heterogeneous* emulsions ceases when the system is made

* This was referred to in Vol. II.

homogeneous by addition of acetic acid, dioxane, pyridine, alkali or bile, but recommences when homogeneity is abolished by addition of water or stronger acid. These authors believe that this reversal demonstrates that the catalysis takes place only in the interfacial film between the water and oil phases, and attribute the observed diminution of the velocity of oxidation by excess of hemin to displacement of linoleic acid molecules from the interfacial film. They conclude that orientation of substrate and hemin molecules in the interfacial film is of decisive importance for the establishment of the catalysis. This is, of course, true, and it involves the electronic contour factor (1) mentioned above; but the kinetic factor (2) is also to be reckoned with.

Biocatalysts; Prosthetic Groups; Symplexes *

The course of chemical change in organisms is directed by catalyst units of colloidal dimensions—enzymes and genes, and perhaps also by units in some symbionts, and units fixed at or on various surfaces. Whereas with primal bionts gene-like units were probably the sole directors of life chemistry, in higher forms we find thread-like aggregations of genes (chromosomes) and a great variety of secondary but highly specific catalysts (enzymes), whose production is in some way interwoven with the activities of the truly living, self-reproducing catalysts. The experimental evidence indicates that large numbers of biocatalyst units are destroyed or inactivated in the course of their functioning, so that there must be a continual replenishment of the supply.

How do biocatalysts arise? The broadest, and therefore the most indefinite answer to this question would be: by the assemblage of smaller units (atoms, molecules, colloidal particles) so as to constitute an exposed surface which has a suitable electronic structure and contour. Genes in the chromosome string thus form duplicates of themselves (autocatalysis),¹³ and must therefore be considered as living. On the other hand, an active catalyst area may be formed by being built into or upon a larger fixed surface, *e.g.*, a cell wall; or else there may be formed by adsorption and/or chemical combination, colloiddally dispersed units—the multitudinous enzymes—which can flow and kinetically “swim” about in cytoplasm, sap, or body fluids, and may even diffuse slowly. Texts often give the erroneous impression that colloids will not diffuse; but Thomas Graham⁵⁰ clearly pointed out that they may diffuse, though they “are slow in the extreme.”

The catalytic effect of the walls of the containers in which chemical reactions are carried out is not, as a rule, sufficiently appreciated, and traces of substances existing in, forming on, or introduced into these surfaces may powerfully influence results. Thus a food product processed in aluminum vessels was deleteriously affected by tiny fragments of iron left in the aluminum surfaces when these were scoured with steel wool. G. Bredig²⁰ found that by fixing amino groups to fibers (cellulose, wool, silk) organic catalysts were produced which split off carbon dioxide from bromcamphocarbonic acid. Although inorganic catalysts may appear to be simple, *e.g.*, platinum black, those having first-hand experience with commercial catalysis know how potent is the influence of structure, carriers, and impurities on the functioning of such catalysts.

Biocatalysts are composed mainly of complex organic molecules, assembled into a delicate but specific structure. When a certain molecular group enters a biocatalyst to form and characterize the active catalyst area, it is termed a *prosthetic* group. The word “prosthetic” is derived from a Greek root meaning to *add to*, or to *insert*. Thus prosthetic dentistry deals with the insertion of missing teeth. The prosthetic group, so to say, puts “teeth” into the biocatalyst. Often the prosthetic group demands for its functioning the presence of a single atom, *e.g.*, magnesium with chlorophyll, copper in the polyphenol oxidase of mushrooms and in tyrosinase,¹⁶ iron in

* See paper by A. E. Axelrod and C. Elvehjem in this volume.

catalase, cytochrome, etc. Where "homeopathic" doses are effective, their action may often be understood along these lines.

Richard Willstätter¹⁴⁶ proposed the term *symplex* for compounds where high-molecular substances are bound by residual valencies, *e.g.*, a prosthetic group and a colloidal carrier. Symplexes are distinguished from mere mechanical mixtures by one or more of the following characteristics: (1) alteration or enhancement of specific reactivity of one component; (2) change in solubility or dispersion of one component; (3) change in optical properties; (4) change in stability; (5) change in toxicity; (6) change in reactions, *e.g.*, color reactions.

True chemical combination is not necessary to make separate units acquire new properties when combined. Neither an arrow-head, an arrow shaft, nor a goose feather is an arrow; but the three, when properly fitted together, will make an arrow and will function as one.^{10, 135} (See also J. Alexander, in Allen's "Commercial Organic Analysis," 5th ed., Vol. 10, 1933.)

Structures of the "symplex" type are very loosely bound together. E. L. Smith¹²¹ found that solutions of phyllochlorins (chlorophyll-protein compounds extracted from spinach leaves) may be split into free chlorophyll and protein by the detergents sodium desoxycholate, bile salts (mainly sodium glycocholate) and digitonin. In the presence of sodium dodecyl sulphate (SDS), the prosthetic group remains attached to the protein, but the compound is split into smaller units, the protein properties and absorption spectrum being modified. Tobacco mosaic virus is also split by SDS into smaller fragments, nucleic acid being simultaneously separated from the protein.¹²⁶ In the presence of SDS chlorophyll loses magnesium and becomes phaeophytin; and this substance, or the chlorophyll (depending on pH), remains attached to the protein, since the prosthetic group is not separated by ultrafiltration, dialysis, or fractional precipitation. Smith believes that much previous work on chlorophyll dealt only with the prosthetic groups of extremely complex specific catalysts. Emerson and Arnold⁵⁰ concluded from photochemical studies that 2,500 chlorophyll molecules form one functional unit in photosynthesis.

The importance of the carrier in the biological field is indicated by the following two examples. Keilin and Mann⁸³ report that peroxidase, which shows great resemblance to methemoglobin, can be considered as a compound of protohematin with a native protein. Peroxidase forms two highly unstable compounds with H_2O_2 , whose decomposition is much accelerated by the acceptor present in plant extract or by the addition of other acceptors, *e.g.*, ascorbic acid, hydroquinone, or pyrogallol. "The same hematin nucleus combined with three different native proteins forms three distinct compounds: methemoglobin, catalase, and peroxidase, which have many properties in common but show, however, striking differences in the nature and magnitude of their catalytic activities." More recently Warburg and Christian¹⁴³ report that the old "yellow enzyme" may really be an artifact resulting from the loss of adenylic acid during its preparation. They describe five different yellow enzymes, some with similar proteins but different prosthetic groups, others with the same prosthetic group but different proteins. The protein/prosthetic group combination is reversible, and it is estimated that one molecule of alloxine dinucleotide can transfer 1440 molecules of O_2 per minute. Vegetables and fruits are "blanched" by steam before being dehydrated, to inactivate enzymes which cause undesirable changes.

This gives us some insight as to the potency and flexibility of the enzymic catalyst systems of living cells, and effectively answers the antiquated gibe of orthodox organic chemists that whenever a biological reaction is to be explained, a new enzyme is invented.

The formation of chlorophyll seems to demand the presence of iron, just as the formation of erythrocytes in man demands the presence of copper. The mode of formation of prosthetic groups is generally obscure,⁸⁶ but it has recently been shown that thiamin (vitamin B_1) is combined with pyrophosphoric acid,¹⁸⁴ and D. E.

Green states:⁶⁰ "There is ample evidence of the existence in animal tissues and microorganisms of enzymes which catalyze the phosphorylation of thiamin as well as the dephosphorylation of diphosphothiamin." Some animals (man) must eat vitamin C; others (rats) can synthesize it, or in any event do without it in their food.

Nature, with infinite time and opportunity for experiment, accomplishes results in manifold and devious ways. Thus the ascidian *Phallusia mamillata*⁷⁰ has an acid blood (3 per cent H_2SO_4) which contains as chromogen a non-dialysable organo-vanadium compound. On plasmolysis this gives a brown solution, which yields, on drying, a dark-blue powder showing over 10 per cent vanadium (two analyses gave 10.36 and 15.4 per cent, but the latter figure is doubtful). Mussels have a manganese-containing catalyst, pinnaglobin. Most crustaceans, including *Limulus* (the horse-shoe or king crab, of antediluvian ancestry) are literally blue-blooded because of copper-containing hemocyanin. A group of African birds known as the Touracous or Plantain-eaters have in their pinion feathers red or crimson patches or portions from which weak alkali or soap solutions will extract a pigment, which, after precipitation by acid, dries to a rich crimson solid³⁴ called turacin. This has been recently proven to be a copper porphyrin compound.²⁰ Over sixty years ago Professor James F. W. Johnston (University of Durham, England) made the following comment:⁸⁰

"The existence of an animal pigment so rich in copper as turacin (about 8 per cent), offers many interesting problems for study. Traces of this metal seem generally diffused in most vegetables and many animals; but here are more than traces—weighable and visible quantities. It is true that these plantain-eaters have been seen to pick up in their native countries grains of malachite, the green mineral carbonate of copper; but we must rather look to the vegetable food they consume as the true source of this metal. And when the copper is ingested, how does it find its way, in the complex pigment of which it is an essential part, precisely to those feathers, and to those barbs of feathers, and to those parts of such barbs, which are red, and not to the black portions? For if one of these feathers is burnt in a Bunsen gas-burner, not till the red part of the feather is reached will the green flash of the copper tinge the flame. However, in the *crest* of the violet plantain-eater (*Musa-phaga violacea*) and perhaps traces in blood of all these birds, turacin, and therefore copper, does occur. Still the whole mystery of this strange pigment is far from being understood."

It has recently been reported that certain molds will not grow in the absence of traces of gallium; and Aguilhon and Sazerac⁵ found that the addition of 0.0001 per cent of uranium acetate to a fermentation mixture of *acetobacter suboxidans* and sorbitol increased the yield of sorbose by 76 per cent.

In an article on the biochemistry of microorganisms C. B. Van Niel¹³⁷ refers to many other cases where trace substances are vital: *e.g.*, molybdenum for the nitrogen-fixing organism *Azobacter*; copper for common molds as well as for higher plants; boron, apparently needed to form borocitrin, related to the flavin pigments and found in microorganisms by Kuhn. Van Niel also tabulates the recent work of various investigators showing the diverse ways in which different organisms split acetate and normal butyrate.

E. C. Auchter,¹⁸ Chief of the Bureau of Plant Industry, U. S. Dept. of Agriculture, in discussing the interrelation of soils and plant, animal and human nutrition, lists some of the "physiological troubles" of plants which can be cured by supplying the necessary small amounts of certain missing but essential elements. It must, of course, be remembered that larger amounts than the tiny optima may be very harmful, as is the case, *e.g.*, with boron. *Magnesium* cures sand drown of tobacco in the soils of the coastal plain; *manganese* cures chlorosis of tomatoes on some calcareous Florida soils, and permits such soils to give improved yields of potatoes, snapbeans,

cabbage, lettuce, peppers, carrots, beets, citrus and corn; *zinc* cures pecan rosette in the South, citrus leaf mottle in California, South Africa, and Florida, little leaf of apples and other deciduous fruits in the West and Northwest, and white bud of corn on the Norfolk and Hernando fine sands of Florida; *boron* cures internal browning of cauliflower and dry rot of sugar beets in Michigan, crown rot of sugar beets in Ireland, die-back of citrus in Africa, internal cork and drought spot of apples in British Columbia, West Virginia and elsewhere, and cracked stem of celery in Florida; *copper*, added to muck soils in Holland and parts of western New York and to organic soils of Florida, improves the growth of several crops; *sulfur* corrects yellows of tea in Nyasaland (Africa), and improves the growth of field crops in Oregon and other areas.

Since animals depend upon plants, "the soil is the mother of all living things." * Deficiency of cobalt⁵⁵ in certain New Zealand soils causes "bush sickness" in sheep, which seems identical with the "pine" of sheep in Scotland. Iodine deficiency leads to goiter in man and beast and caused an annual loss of thousands of pigs in Montana until iodine feeding was practiced. Selenium, taken from the soil by plants, causes disease and malformations in animals eating the plants.^{97a} Marco Polo, on his journey to Tartary, observed hoof deformations of this type, which may have had the same kind of origin. According to A. L. Moxon traces of arsenic compounds, fed in water or in salt, tend to protect animals against the toxic action of selenium, while bromo-benzene aids in its excretion.

The eighth scientific meeting of the Nutrition Society held in London, England, Oct. 17th, 1942, was devoted to "Trace Elements in Relation to Health." Among the rarer deficiency diseases mentioned are: enzootic ataxia (swayback of lambs), which may be prevented by feeding traces of copper during pregnancy; molybdenosis (called teart of Somerset), which affects ruminants, due to molybdenum taken up by plants where the soil content of molybdenum was about 100 ppm, and helped by traces of copper sulfate; fluorosis, which may cause osteosclerosis, though teeth with mottled enamel due to fluorine are relatively immune to caries.

It must not be supposed that trace substances always operate in one way, for the complications in any case may be great. Thus sulphur may be oxidized by soil bacteria and affect the local pH—from which a chain of other consequences may follow. However, much of the evidence points to the conclusion that the inclusion of trace substances in catalyst surfaces is a frequent factor that must always be considered; for visible results develop from the products of catalysis.

Biocatalyst Systems or Chains

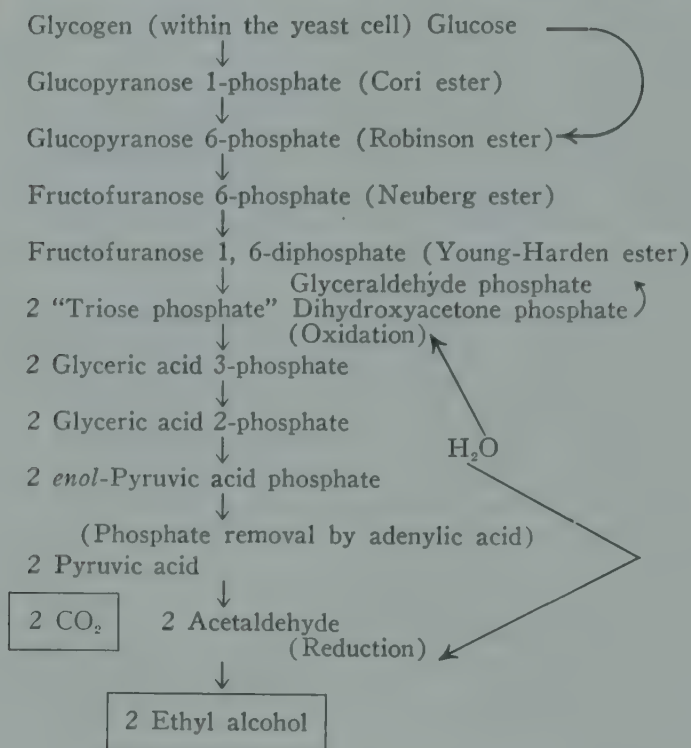

It is we who are simple, not nature. The physico-chemical happenings at various structural levels, which underlie the phenomena we observe, are numerous, intricate, often obscure, sometimes unsuspected. The complications involved in the structure, lability, and functioning of individual enzymes are magnified in cells, tissues, and organisms, where groups of catalysts and coöperative chemicals form chains or systems which have not yet been constructed for experiments *in vitro*. Isolated enzymes, supposed to be pure, have sometimes proven to be mixtures, and it is always a question as to how far experiments with pure enzymes may be applied to an intact biological unit. Liver slices energetically oxidize certain of the lower fatty acids, but when the liver is minced this power immediately disappears.^{60, p. 165}

As an illustrative instance, we may take the fermentation of glucose by yeast,⁹⁹ widely practiced and long studied. Present experimental data justify the belief that underlying the extremely naive equation

* This statement is too sweeping, even though many forms of sea-life depend upon substances washed into the seas from the land.

the following catalyzed system is operative (end products shown in rectangles):

The successive steps tabulated are catalyzed by specific enzymes,* and many of the changes have been shown to be reversible. Besides the final products (ethyl alcohol and carbon dioxide), a small amount of glycerin is also produced. A somewhat more detailed table is given by O. Meyerhof in *Biological Symposia*, 5, 141-155 (1941).

Since the formation of Cori ester from glycogen is inhibited by glucose, enzymic formation of glycogen within the yeast cell, along the lines shown by C. S. Hanes,⁶³ may serve to restrict glucose concentration as glucose diffuses into the yeast cell.

If sodium sulfite is added to a yeast fermentation, the formation of alcohol practically ceases and the small percentage of glycerin which occurs in normal fermentation increases so that it becomes a main product, with acetaldehyde and carbon dioxide. The acetaldehyde is fixed by the sulfite, the CO_2 is liberated, and the glycerin remains; during the war which began in 1914, Germany produced glycerin by fermentation processes. Bell²⁰ states that the traces of glycerin in normal fermentation are due to the "mutase" system in the yeast cells. It seems that, normally, acetaldehyde acts as a hydrogen acceptor in the anaerobic oxidation of triose phosphate; but when the acetaldehyde is removed by the sulfite present, another molecule of triose phosphate can act instead. Since the former reaction is the more rapid, little glycerin is formed when acetaldehyde is present.

By carrying out the fermentation at an alkaline pH, Neuberg found that the breakdown of the glucose yielded glycerin, alcohol, and acetic acid, according to the following scheme,⁶⁰ which is not yet understood in detail:

* According to A. B. Gutman, F. B. Warrick and E. B. Gutman [*Science*, 95, 461 (1942)] three enzymes are present in calcifying cartilage, *viz.* phosphorylase, phosphatase and phosphoglucomutase, which act on glucose-1-phosphate. The calcification process is carried further by a glycolytic enzyme system [G. M. Hills, *Biochem. J.*, 28, 864 (1934)].

Not only does the apparently simple yeast cell contain a considerable number of specific enzymic catalysts and collaborating molecules, but it can be "trained" to ferment galactose,⁴³ by adding small and continually increasing percentages of this sugar to the fermentation mixture. Evidently yeast can "manufacture" new enzymes to meet new situations; probably the new substances add their own specificity to a system of molecules to make a new prosthetic group.⁸

Karström⁸¹ divided the enzymes of microorganisms into two groups; (1) *constitutive enzymes* whose formation is common to all media; (2) *adaptive enzymes*, which are formed only when the cell is "stimulated" by the presence of a specific chemical substance in the milieu, a procedure which seems to be analogous to the formation of antibodies in animals.^{113, 8} Experimenting with nine strains of yeast (*Saccharomyces*), Rhoades¹¹⁵ found that each one could ferment glucose, mannose, sucrose, and raffinose "regardless of the carbon source in which the cells had grown; that is, these sugars were fermented by constitutive enzymes." On the other hand, maltose, trehalose, alpha-methylglucoside and galactose* were fermented only if the organism was "trained" by growth in the presence of the specific substrate or a closely related substance, that is, after the formation of adaptive enzymes.

Crystallization Phenomena

The crystallization of substances formerly believed to be non-crystallizable has astonished many who fail to remember that orderly arrangement in a space lattice is a potential minimum which molecules *tend* to assume, although conditions often enforce the persistence of some intermediate state. Furthermore, misleading texts engendered the erroneous notion (which still persists) that crystalloids constitute a class of *substances* quite apart from the "non-crystallizable colloids," even though Thomas Graham, who coined the word "colloid," had stressed the mutability of the colloidal *state* of matter, and had pointed out that the same substance, *e.g.*, silica, can exist both in crystalline and in colloidal form.

In their natural state many "natural colloids" are probably prevented from establishing their tendency to form a visible crystal lattice by their own inherent and variable complexity, by the presence of protective or deflocculating substances, or by the ionic concentrations of their milieu *e.g.*, pH. By suitable purification and choice of conditions, even rubber hydrocarbon has been crystallized,¹²² and P. P. von Weimarn held the view¹⁴⁴ that any substance can be made to assume both the colloidal and the crystalline states. The x-ray spectrometer shows that many colloids are cryptocrystalline, and the ultramicroscope and the electron microscope bring out the assemblage of units at higher structural levels.

According to Professor G. W. Stewart,¹²⁸ the x-ray and other evidence indicate that the molecules in the interior of a liquid are found, roughly, in one of two classes: (1) those having comparative freedom; (2) those in semi-orderly array, strongly imitating fragments of crystals. He terms these fluctuating molecular "mobs" *cybotactic groups*, which, in the case of *liquid para-azoxyanisol*, may consist of perhaps 100 to 1000 molecules. In the *liquid crystal* of this substance these companies are ordered into regiments composed of perhaps millions of molecules.

* One strain, *S. cerevisiae* Hansen, possessed the inherent ability to ferment galactose.

Crystallization involves orderly molecular assemblage, and often occurs in the following stages: (1) with drop in temperature or evaporation of solvent, molecular aggregates of colloidal size form under the laws of chance, just as the Faraday-Tyndall haze forms in a condensing gas;⁴⁹ (2) these aggregates, which may be crystalline, have a diminished kinetic activity and tend to form spherulites under the influence of surface forces; (3) owing to residual polarity, the spherulites tend to form chains or quasi-crystalline groups which strive toward and often attain the potential minimum of a crystal lattice.⁷

All these stages of crystallization may be found, here and there, in window-pane ice, but they may be produced at any time with a solution of sulfur in carbon disulfide to which has been added some Canada balsam to slow down the velocity of the steps and to fix the results. A drop of the solution is placed on a microscope slide, spread out with the finger and blown upon to speed evaporation of the solvent. On microscopic examination of various fields one generally finds areas showing spherulites, margarites (dendritic, pearl-like chains of spherulites), spherulites in crystal-like array, and well-defined crystals. Upon ultramicroscopic examination, the crystals often show at their exterior ultramicrospheres or spherulites which failed to find lodgment in the crystal lattice.^{7, 19, 52}

Molecular Assemblage in Proteins *

Proteins are subject to aggregative changes apart from actual crystallization. Thus I.-B. Eriksson-Quensel and The Svedberg⁵³ found that the molecules in a solution of the hemocyanin from the snail *Helix pomatia*, show a molecular weight of 6,740,000 when slightly acid (pH 6.8); but when made slightly alkaline (pH 8.0) the protein splits into three components whose molecular weights are 6,740,000, 3,370,000, and 842,000 respectively. On restoring the pH to 6.8, all the fragments of dissociation completely unite to form the original component. Dissociation of proteins may be brought about by high dilution or by the addition of an amino acid or another protein.¹⁰⁹ So minute an amount as 0.001 per cent of thyroxine causes an appreciable dissociation of thyroglobulin (H. P. Lundgren, from T. Svedberg¹³⁰).

The Svedberg states¹³⁰ that the action of a dissociating compound on a protein is more or less specific. Thus in the presence of ammonium chloride, arginine dissociates serum albumin but not *Helix* hemocyanin, while lysine plus ammonium chloride splits the latter protein but not the former. Guanidine chloride affects *Helix* hemocyanin very strongly, but serum albumin only slightly. Clupein splits both proteins, but arginine, in the absence of ammonium chloride, affects neither.

These and other experiments of Svedberg and his school show how delicate is the physico-chemical mechanism controlling the particle size of proteins, and indicate how slight changes in biocatalysts, by determining the formation of even traces of specifically potent substances, may exert profound effects on protein structure and function, *e.g.*, as carriers or as prosthetic groups. Particle size and structure will, in turn, determine kinetic activity, diffusion, and the extent and nature of the outwardly directed electronic mosaic. With the biologically important colloid proteins, as indeed with most other substances, we must, at a certain stage of organization, envisage the possibility of particulate unions and dissociations which are not explicable in terms of simple stoichiometry, even though they are due to residues of those same sub-atomic potencies which account for chemical attraction. There comes a zone in the successive levels of increasing complexity of material structure, where the external electronic mosaics of the particles may be somewhat variable and affected by adsorbed "impurities," and yet the attraction—or repulsion—of the particles may be biologically important, although not as powerful or as precise as with true chemical combination between smaller, less highly organized particulate units.

Svedberg and his school have given particular attention to the physiologically

* See paper by W. T. Astbury in this volume.

important *respiratory proteins*, which are also of great interest from the physico-chemical as well as the taxonomic point of view. In epitomizing this work, Svedberg¹³⁰ distinguishes between: (1) respiratory proteins active in cells—*viz.*, Keilin's cytochrome-C, Warburg's yellow enzyme,* and myoglobin, often called muscle hemoglobin, for it takes up and gives off oxygen along a dissociation curve and probably serves as an oxygen reservoir for the organism; the first two are true respiratory cell proteins, taking part in the enzymic oxidation-reduction reactions; (2) respiratory blood proteins active in external respiration, which fall into the following classes:

- (a) red pigments (erythrocruorins, hemoglobins)
- (b) green pigments (chlorocruorins)
- (c) blue pigments (hemocyanins)
- (d) reddish-brown pigments (hemerythrins)

Classes (a) and (b) have similar prosthetic groups containing iron, and are called hematic chromoproteins; they can take up one molecule of oxygen for each atom of iron. With class (c) the prosthetic group contains copper, and these proteins can take up one molecule of oxygen to two atoms of copper. With class (d) the prosthetic group also contains iron, but the oxygen-binding capacity is one oxygen molecule to three atoms of iron.

The cellular respiratory proteins, cytochrome-C and myoglobin, both contain iron in their prosthetic group and have almost the same molecular weight, about 17,000, which equals that of *Lampetra* erythrocruorin and is one-fourth the weight of the normal hemoglobin of vertebrates.

With one exception, the respiratory pigments enclosed in blood corpuscles have small molecular weights, whereas those dispersed in the plasma have large ones. All vertebrates, except species belonging to the lowest class, the *Cyclostomata*, have in their blood corpuscles a protein pigment of the same molecular weight, 68,000 (hemoglobin) with four iron atoms per molecule. With *Cyclostomata* the corpuscle pigment has a molecular weight only one-fourth that of hemoglobin, and according to A. Hedenius, certain invertebrates have a corpuscle erythrocruorin one-half the molecular weight of hemoglobin. Mammalian hemoglobin dissociates reversibly into half-molecules upon addition of certain amino compounds such as urea, acetamide and formamide. The hemoglobin synthesized by Anson and Mirsky from globin and heme, though it had the same molecular mass as the native protein, showed a slightly lower isoelectric point (N. Gralén). The chemical processes employed, therefore, had registered some lasting effect. Erythrocruorins of high molecular weight are found in the blood plasma of the crustacean *Daphnia*, ($M = 400,000$), of the snail *Planorbis* ($M = 1,600,000$), and of certain worms, *Arenicola*, *Lumbricus* ($M = 3,200,000$).

"The hemocyanins form an interesting class with a number of inner connections. The molecular weights of the hemocyanin molecules found in the blood of certain species are always simple multiples of the lowest well-defined component. Thus, for the *Malacostraca* the relationship is 1:2 and for the *Gastropoda* 2:8:16:24. Moreover, the weights of all the well-defined hemocyanin molecules seem to be simple multiples of the lowest among them. In most cases the hemocyanin components of certain species are interconnected by reversible, pH-influenced dissociation-association reactions. At certain pH values a profound change in the number and percentage of the components takes place. The shift in pH necessary to bring about reaction is not more than a few tenths of a unit. Consequently, the forces holding dissociable parts of the molecule together must be very feeble.

"Not only the molecular weights of the hemocyanins but also the mass of most protein molecules—even those belonging to chemically different substances—show a

* This has recently been separated into five enzymes, the original yellow enzyme having proven to be an artifact.¹⁴³

Molecular Constants of Proteins

According to measurements carried out in the Institute of Physical Chemistry, University of Upsala, Sweden. As of Nov., 1942.
Kindly supplied by The Svedberg and Kai O. Pedersen, Upsala University, Sweden.

V_{20} = partial specific volume of the protein. (The values in brackets are assumed values based on experimental determinations on closely related proteins.)
 s_{20} = sedimentation constant = $\frac{dx}{dt} \cdot \frac{1}{\omega^2 x}$, in units of 10^{-13} reduced to water at 20°C .
 D_{20} = diffusion constant in units of 10^{-7} reduced to water at 20°C .
 M_s = molecular weight computed from sedimentation velocity and diffusion measurements according to the formula:

$$M_s = \frac{RT s_{20}}{D_{20}(1 - V_{20}\rho^0)}$$

M_e = molecular weight computed from sedimentation equilibrium measurements according to the formula:

$$M_e = \frac{2RT \ln (c_2/c_1)}{(1 - V_{20}\rho^0)\omega (x_2^2 - x_1^2)}$$

M_{calc} = molecular weight calculated from the rule of simple multiples.

f/f_0 = ratio of experimentally determined molar frictional constant f = $\frac{M(1 - V_{20}\rho^0)}{s_{20}}$ to molar frictional constant calculated for an un-

solvated spherical particle of the same mass $f_0 = 6\pi\eta^0 N \left(\frac{3MV}{4\pi N}\right)^{1/2}$

$\frac{du}{d\phi H}$ = slope of mobility curve in the vicinity of the isoelectric point.

R = gas constant = 8.313×10^7 erg grad $^{-1}$.

N = Avogadro constant = 6.06×10^{23} .

T = absolute temperature.

ρ^0 = density of water at 20°C = 0.9982.

ρ = density of solution.

η^0 = viscosity of water at 20°C = 0.010.

c = concentration.

x = distance from axis of rotation.

$\frac{dx}{dt}$ = sedimentation velocity.

ω = angular velocity of rotating solution.

¹ Except when otherwise stated, the values refer to experiments carried out at 20° C in acetate or phosphate buffers with ionic strength = 0.02. The determinations marked with * were carried out under the same conditions, but at 0° C.

² The specific volume of gliadin varies strongly with the protein concentration according to Krejci and Svedberg (1935). For the calculation of *M*, Lamm and Polson (1936) used *V* = 0.722.

³ Mean value obtained by a number of different observers in Upsala.

⁴ Recalculated to water basis.

⁵ Mean of two determinations on CO-hemoglobin and two on methemoglobin.

⁶ Mean value for the A and B fractions prepared by Kekwick (1938).

⁷ Total serumglobulin obtained by half-saturation with ammonium sulfate.

⁸ Electrophoretically prepared γ -globulin from normal human serum.

⁹ Mean of four determinations on four different specimens.

similar relationship. This remarkable regularity points to a common plan for building up the protein molecules. Certain amino acids may be exchanged for others, and this may cause slight deviations from the rule of simple multiples, but on the whole, only a very limited number of masses seems to be possible. Probably the protein molecule is built up by successive aggregation of definite units, but only a few aggregates are stable. The higher the molecular weight the fewer are the possibilities of stable aggregation. The steps between the existing molecules, therefore, become larger and larger as the weight increases. These statements are borne out by Table 1, in which are collected recent data for the various constants of protein molecules as determined in Upsala."

Modification of Biocatalysts

The writer has taken the view that biocatalysts are subject to *modification*, which involves the fixation, at an active catalyst area of a gene or other catalyst unit, of some particle (electron, ion, atom, molecule, or colloidal particle) which changes the nature and/or the rate of the catalytic change occurring there.⁸ A *limiting case* under this general principle would be the *formation of a new catalyst area* by the fixation, *e.g.*, at a protein surface, of a prosthetic group. In the case of genes a change in catalytic output may arise from an intraparticulate change* in the gene itself (known as a *point mutation*), or because of some chromosomal upset (*e.g.*, inversion, translocation, crossing over) which places the gene in different surroundings (*position effect*). If heritable and non-lethal, both of these types of change generally lead to new mutant forms of plants or animals. The modification of enzymes within a cell, or the formation or introduction of new enzymes there, could lead to catalytic variations of chemical output which might simulate the effects producible by a point or a chromosomal mutation; but the result would be transient unless sufficient of the modifiers and prosthetic groups to maintain it were supplied or produced. Another possibility is that a specific area may serve as a template or mold against which may be formed specific catalytic molecular structures or plaques. Still another possibility is the local establishment of ionic or trace-substance conditions favorable to the formation of new enzymes, *e.g.*, by adsorptive fixation of a prosthetic group by a carrier. Viruses and bacteriophages reproduce themselves in cells, thus (where they exert catalytic action) behaving *as if* they were free-living genes. What is said of genes may be applied with equal force to mitochondria; for whether these are symbionts or cytoplasmic inclusions, they apparently reproduce and are efficient in directing chemical changes within the cell (either directly or through enzyme formation), and behave somewhat as if they are free-living genes or gene groups.

The stability of genes and the efficiency of the protections surrounding them are evidenced by the regular and orderly sequences normal to life, which show that gene mutations are relatively quite rare, and abnormal gene or catalyst modifications unusual. Since non-lethal gene mutations may be transmitted by heredity, they are basic factors in evolution; for beneficial mutations tend to survive and dominate, whereas harmful ones tend to die out. If mutation makes a gene (or other catalyst) more susceptible to an abnormal modification, that is one way in which the effect of a mutation may become evident.

Bacterial Dissociation and Transformation^{93b}

The colonies of most bacteria that have been studied may appear in a rough, corrugated form (R), or in a smooth, glistening, drop-like form (S). The change of a culture from R to S, or *vice versa*, is known as *dissociation*.⁶² The methods used to produce dissociation involve, mainly, change in the usual growth medium: (1) by the addition of sera, normal or immune; (2) by addition of definite chemical agents

* With or without particulate additions.

(e.g., LiCl_2 , FeCl_3 , sodium taurocholate); (3) by change in pH; (4) by animal passage, a method much used, involving considerable, though unknown, changes in the culture medium. For example, Alexander-Jackson¹⁴ was able to change two strains of human tubercle bacilli of R form over into S forms by the addition of 0.0004 per cent of ferric chloride to Bordet-Gengou medium. As a rule, the S form is relatively more virulent than the R form of the same strain. At the laboratory of the New York City Board of Health the virulence of test strains of pneumococci is maintained by daily passage through mice, to give an example of the well-known effect of animal passage, which also exerts changes in the virulence of viruses; e.g., the virulence of smallpox to man is reduced by passage through cattle.

On the other hand Herald R. Cox^{86a} found that the virulence of a *Dermacentor variabilis* strain of Rocky Mountain spotted fever was enhanced, as against guinea pigs, upon growth in the yolk sacs of developing chick embryos. The virulence decreased after about 50 passages, and after about 100 passages the strain, while causing slight or no reaction in the guinea pigs, made them "solidly immune to massive doses of highly virulent strains." See, also, R. E. Green^{60a} on the nature of virus adaptations.

Griffith,⁶¹ working with white mice, discovered the interesting fact that S forms of pneumococci can be transformed from one specific type * into other specific types through the intermediate stage of the R form. Since the specificity of the types involves the formation of specific substances, (especially, as Heidelberger⁶⁹ has shown, specific carbohydrates), it seems obvious that the catalysts of the pneumococci in Griffith's experiments must have undergone a change; either old catalysts were transformed, or new ones were formed.

Dawson and Sia,⁴¹ working *in vitro*, found that R forms of pneumococci derived from S forms of one specific type (Type II), can be transformed into the S forms of other specific types (Types I or III), by growth of small inocula of the R form of Type II in media containing vaccines prepared from heterologous S cultures. It seems possible that in this case the R form contains an enzymic carrier which has been deprived of its prosthetic group, but which takes up a different prosthetic group from the new vaccine-containing medium. That these R forms are more labile is brought out by Sia and Dawson,¹¹⁹ who state: "R cultures possessing only slight degree of R stability are most suitable for transformation purposes by *in vitro* procedures."

In cultures of *Hemophilus influenzae*, *Escherichia coli*, and *Streptobacillus moniliformis*, the germination of "large bodies" has been observed, and the descendants of these "L type" colonies, instead of resembling the parent organism, are similar in both morphology and development to the pleuropneumonia group of organisms. Such "L type" colonies come from strains which are rare in most species, but they were also observed in cultures of a *Flavobacterium*, of *Bacteroides funduliformis*, and of the gonococcus, and have been isolated in pure cultures from the two former. L. Dienes^{44a} believes that they represent a variant type, in which case the variability of bacteria extends much further than is commonly supposed. E. Kleinberger (references in Dienes' paper) thought that they represented symbionts, a view that Dienes opposes. The question is not finally decided.

Speaking of the enzymatic synthesis of polysaccharides, M. Stacey† states: "There is good evidence for the theory, here advanced for the first time, that the synthesizing enzyme remains in combination with the polysaccharide it has synthesized, and there is progressively built up a complex macromolecule in which com-

* At present, 50 specific types of pneumococci (40 numbered types and 10 sub-types) have been identified. Besides these, other bacteria may produce pneumonias; e.g., Friedlaender's bacillus, streptococci, and the influenza bacillus of Pfeiffer. (J. G. M. Bullowa).

† "Mucopolysaccharides and Related Substances," *Chemistry and Industry*, 62, 110-112 (1943).

paratively short polyglucose chains are 'cemented' together by a nucleoprotein. In the case of one dextran from *Betabacterium vermiciforme* (Ward-Meyer), the aggregating process can go on until the macromolecule is so large that it settles out of the solution in the form of granules. The separation of granular synthetic starch takes place in precisely the same manner and the product contains significant amounts of a nitrogenous constituent which could only come from the phosphorylase preparation."

Evidence that bacterial catalysts direct the formation of specific polysaccharides appears in the statement of E. J. Hehre^{68a} and J. Y. Sugg that a serologically reactive polysaccharide of dextran nature was produced from sucrose by sterile filtered extracts derived from sucrose broth cultures of *Leuconostoc mesenteroides*, a Gram-positive coccus widely distributed on plants. "Rigorous controls were included to prove that this reaction occurred in the absence of microorganisms." The polysaccharide was recognized chemically and also by its ability to react with the anti-serums of types 2 and 20 pneumococci, as well as with the antiserum of the homologous bacteria.

These and many other facts support the view that the specificity of all species, both plant and animal, stem from, or at least involve, differences in the basic biocatalysts. The visible forms with which taxonomy deals, and even the specific substances which biochemists isolate and identify, are mainly an aftermath. The basis of species specificity and even of evolution rests largely on biocatalysts and their changes.

Immunology

Immunological specificity, like all other kinds of biological specificity, depends on the outwardly directed specific electronic fields of the units involved in agglutination, precipitation, lysis, anaphylaxis, etc. With egg albumin the minimum sensitizing dose is about 0.000,05 milligram; and in general, the tiny quantities of antigen demonstrable by immunological methods cannot be detected specifically by other known methods. How shall we account for these potent and highly specific effects of incredibly minute quantities, and also for the fact that, when an immunized animal is bled, the temporary drop in the titer of antibodies in the remaining blood is soon retrieved and often surpassed? The reactivity of a sensitized animal or even of its tissues is not impaired by replacement of its blood by the blood of a non-sensitized animal.

The experimental facts point to *the formation, within the cells or tissues, of new specific catalyst surfaces which are able to direct the formation of antibodies.*^{8, 12} Marrack⁹⁴ states that the properties of antibodies indicate that they appear to consist of modified serum globulin; and that on immunization there may be an increase in serum protein, mainly in the globulin fraction. While nature may utilize any conceivable or unthought of method, it seems most likely that the antigen particles serve as prosthetic groups in the formation of biocatalysts which can determine the formation of units having *essentially the reverse electrostatic charge pattern of the antigen*^{8, 12} in their exposed surfaces, when they are detached or removed, perhaps by the dominant attraction of a carrier, or by action of a "detergent" substance in the milieu, or by reaching a critical thickness.⁵⁸

The specificity and lasting effects of minute quantities of antigens become comprehensible on the basis of this view, for in theory one single molecule would suffice to form or convert a biocatalyst particle into a producer of specific antibody. In fact, Kuhn, Moewus, and Jerchel⁸⁷ report that one single crocin molecule is capable of inducing a sexual change* in a whole alga. There is no reason why many different antigens may not thus simultaneously or successively produce their own

* Oysters change sex as they grow older. Sex change in plants is also known,^{111a} e.g., in the Florida silver palm.

specific catalysts and antibodies, even in the presence of numerous enzymes and genes; and this checks with the experimental facts. The specific "mold," once formed, could function continuously, despite bleeding, unless irreversibly injured. Variations in the duration of immunity would follow variations in the persistence in functioning of the new "antigen catalyst," while inability to establish immunity could be due to destruction of antibody, or to inability to form a biocatalyst for its production, *e.g.*, because of lack of a suitable carrier substance. All these phenomena appear in "vaccination," a general term indicating introduction of antigen with the hope that immunity will result.

In discussing the nature of the intermolecular forces operative in biological processes, L. Pauling and M. Delbrück state:¹⁰⁶ "It is our opinion that the processes of synthesis and folding of highly complex molecules in the living cell involve, in addition to covalent-bond formation, only the molecular interactions of van der Waals attraction and repulsion, electrostatic interactions, hydrogen-bond formation, etc., which are now rather well understood. These interactions are such as to give stability to a system of two molecules with complementary structures in juxtaposition, rather than to two molecules with necessarily identical structures; we accordingly feel that complementariness should be given primary consideration in the discussion of the specific attraction between molecules and the enzymic synthesis of molecules." Pauling has worked out in further detail a theory of the structure and process of formation of antibodies, and has discussed the mechanism of their union with antigens.¹⁰⁷

Later, Pauling and Campbell described the formation of antibodies *in vitro*.^{107a} "The procedure consists in subjecting normal globulin or other protein to the action of denaturing reagents or conditions in the presence of the antigen. The protein molecule unfolds, and then refolds in such a way as to assume a configuration complementary to that of the antigen, thus acquiring the properties of a specific homologous antibody."

It is not necessary to think of antibodies as simple molecular units, or to imagine that the *whole* of the antibody area is specific to the antigen. Thus, as Landsteiner has shown, atoxyl became a "determinant group" in each of the antibodies synthesized by combining it with various proteins by a diazo reaction. The protein serves as a carrier, and the atoxyl (though not of itself an antigen) becomes a determinant group or *haptén*, which, in some respects, exercises a determinative function analogous to that of the prosthetic group in an enzyme.¹⁸⁵

A hapten impresses upon its antibody a specificity which leads to the combination of the antibody with its specific antigen; but in some cases closely allied determinant groups are immunologically equivalent. The antibody, and perhaps also the antigen after it enters the animal, may be considered as a *plaque* having surface specificities, wherein the subunits may be held together by forces less potent than those of primary valency.

The functioning of the antigen "mold" or "template"^{95a} may be crudely illustrated, at a much higher structural level, by pressing a piece of tinfoil against the surface of a coin.* The surface of the foil *next* to the coin acquires an impression which is the specific *opposite* or reverse intaglio of the coin pattern, while the *upper* surface of the foil acquires a surface impression which *duplicates* the coin pattern. If something analogous occurs when a molecular plaque is formed against an antigen mold, the subsequent influence of the detached plaque would depend upon *which of the plaque surfaces remains exposed to the milieu*, if the plaque serves as adsorbent or is itself adsorbed. There could thus be formed a new surface like the mold, or a surface with reverse contour, or modifications of either of these surfaces if the

* The writer has used this as a lecture illustration for over ten years. See J. Alexander, "Colloid Chemistry," 4th ed., p. 385, D. Van Nostrand Co., 1937.

plaque is distorted on adsorption or is subject to enzymic or other biochemical attack.

The separation of duplicated chromosomes during mitosis shows that forces exist which separate the duplicated gene-strings from each other. As N. K. Koltzoff⁸⁵ and C. B. Bridges³⁰ independently showed, the huge salivary gland chromosomes in the small grub that develops into *Drosophila*, which are enlarged or swollen to about 200 times normal size, appear to consist of a number, possibly 16 or more, gene strings which, instead of separating, remain coherent and, when stained, show specific bands and structures at the loci of specific genes. On comparing the locations of these bands with the gene maps developed from the data of geneticists, their matching indicates that we have before us what has been termed a "genetic spectrum."¹²

What forces normally separate each template gene from the new gene formed against it, so that the new chromosome may separate lengthwise from its originator? And what forces would determine the separation of our hypothetical plaque from the surface against which it was formed? While no simple or positive answer can be given, it must be recalled that small changes in ionic concentration (pH with protein units, C_{Ca} in the developing zygote) could be effective, as may also be the presence of small amounts of specific substances which act as "detergents," as Svedberg found with proteins and as Smith found with natural chlorophyll. Another possibility is suggested by the experiments of Goranson and Zisman,⁵⁸ who found that when about 500 successive X-multilayers of calcium (or barium) stearate were deposited upon an ebonite "probe," the polymolecular layer spontaneously detaches itself.* Possibly the cohesive surface forces diminish as the layer becomes thicker, and are no longer effective when the deposit reaches a critical thickness. It is not unreasonable to envisage the possibility that specific natural proteins, carbohydrates etc., may be thus formed at the surface of specific catalysts as templates, and float away to become effective units elsewhere. A contrary effect seems to be produced by colchicine, which causes chromosome doubling or polyploidy, apparently by interfering with spindle formation during mitosis.†

On the other hand C. C. Lindegren and C. B. Bridges^{89a} advanced the hypothesis that the surface of each chromomere (not necessarily the gene surface), may stimulate the protoplasm to form specific antibodies, which on being specifically adsorbed at the chromomere interface, renders it capable of adhering specifically to its partner chromomere in synapsis. Any two allelic chromomeres happening to touch "would be cemented together by the antibody junctions specific to themselves. The chromomeres which are on each side of the already agglutinated ones would then be more likely to touch and fuse, so that synapsis would proceed, zipper-like, from the first points of homologous contact throughout the entire lengths of the chromosomes." (See below, Topley, Wilson and Duncan).

Differentiation and the Orderly Course of Life

The self-duplication of a particle of molecular or near-molecular dimensions, e.g., a virus, a gene, or a hypothetical molecubiont, can be understood as an assemblage of subunits ordered by the "progenitor" particle into its own precise structure. However, when we consider the development of a plant or an animal from a zygote,

* The authors say: "In plating X-multilayers it has been observed that after about 500 layers have been deposited, and the electrostatic repulsive field of the multilayer has thus reached a certain value, the upper portion of the submerged probe has a silvery appearance which gradually moves down the probe with increasing number of dips, and film does not adhere to the multilayer over this portion. This electrostatic repulsive field thus sets a limit to the thickness of X-multilayers on insulators." Dr. Goranson informs me (private communication) that "if plating is made on a metal, more layers can be put on because of the oppositely induced charge on the metal."

† See paper by W. D. Harkins in this volume.

a single fertilized cell resulting from the union of a male with a female gamete, we are confronted with the astounding fact that there emerge, in regular order, a variety of cells, tissues, organs, and bodily structures, generally possessed of highly specialized functions, and thus *differentiated* from the original zygote cell.* Under normal conditions, the developing zygote follows, with surprising precision, the devious transformations leading to the completed organism, the possibility of whose formation was foreordained subject, of course, to the presence of a suitable milieu, by the genes and cytoplasmic inclusions entering into the zygote from the parents.

It seems evident that the definitely directed course of differentiation cannot be accounted for by assuming that there occurs a suitable series of gene point mutations, each appearing at the proper time; for point mutation is sporadic and more or less indefinite. The view has been advanced,⁸ and is here maintained, that *the formation and/or the modification of definite biocatalysts*, at definite times or stages, by definite chemical substances mainly included in the zygote cytoplasm, or subsequently formed catalytically, will reasonably account for these orderly happenings. While many other factors are operative, and intercurrent substances (or lack of them) in the milieu are important, no other basic phenomenon seems to offer so satisfactory an explanation of differentiation as does catalyst formation and/or modification.

In attempting to outline certain physico-chemical principles which are operative in the clone † of cells developing from the original zygote, it must be emphasized that not only is each system in itself highly complex, but also that very wide differences appear in the details and order of development with the numerous varieties, species, and genera of plants and animals. With many forms it appears that in the zygote itself an initial segregation of modified or of modifying substances occurs. The slight differences often found in monozygotic twins^{9a} do not seem to be due to the precisely duplicated genes, but rather to inequalities in the apportionment of the zygote cytoplasm upon mitosis, involving unequal distribution of catalyst modifiers between the cells, which later develop into separate individuals.

As the clone of cells arising from the zygote increases in size, certain physico-chemical situations must naturally develop in the rounded mass of cells termed the blastula. Whereas with a single cell diffusion of materials to and from the cell is relatively rapid and equalized, with a mass of cells a *diffusion gradient* tends to appear, cells and even portions of cells at the exterior having a more favored position relative to cells on the interior. Ions, molecules, and even colloidal particles differ greatly in diffusibility, and as a consequence of differential diffusion⁹ there appear zones of variation in ionic and molecular concentration which can exert profound influence on such factors as the formation and functioning of biocatalysts, the adsorbability of prosthetic groups and modifiers, the structure of proteins, and the aggregation of colloids. The intense particulate activity revealed in cells by the ultramicroscope may in part be due to diffusion at catalyst surfaces, the convection being intensified in interior cells if a thermal gradient exists there.

Kenneth B. Raper ["Third Growth Symposium," 41-76 (1941)] describes the remarkable behavior of simple slime molds, which live and multiply by fission when

* As Prof. R. G. Harrison points out this ever-recurring wonder is thus expressed in the 139th Psalm:

"14. I will praise Thee; for I am fearfully and wonderfully made: marvelous are Thy works; and that my soul knoweth right well.

15. My substance was not hid from Thee, when I was made in secret, and curiously wrought in the lowest parts of the earth.

16. Thy eyes did see my substance, yet being unperfect; and in Thy book all my members were written, which in continuance were fashioned, when as yet there was none of them."

† The term *clone* (sometimes spelled *clon*), indicates a cluster of cells descended from a common progenitor. It is derived from the Greek word *klon*, meaning *a twig*, which is apparently the root word for the Gaelic *clann*.

plenty of food is available. Following this vegetative stage, masses of cells, which may number as high as 150,000, gather together to form a pseudoplasmodium which migrates as a unit but stops, in *Dictyostelium discoideum*, just preceding formation of the sorocarp (spore-bearing stalk). The constituent myxamoebae collect into a rounded apiculate mass whose basal part is first differentiated near the center of the mass. "Somewhat above the level of the substratum a hyaline tube is developed and within this the cells become vacuolated and compacted together. It is not known whether this membrane, or sorophore sheath, is formed by the myxamoebae contained within it or by those surrounding it, for the myxamoebae on either side appear equally undifferentiated. In either case, however, it is the product of multiple cells and represents a function of the whole mass, for its diameter is regularly proportional to the size of the entire body. As the myxamoebae within it begin to differentiate, the sheath is extended upward and downward. . . . The upward elongation of the sorophore continues by extension of the slime sheath and by the differentiation within it of myxamoebae into stalk cells. In the area of sorophore formation progressive stages in the progressive differentiation and vacuolation of myxamoebae into parenchyma-like stalk cells occur from the apex downward. As the sorophore elongates the mass of myxamoebae ascends or is carried up by the developing sorophore . . . the myxamoebae at its periphery and in contact with the air begin to differentiate into spores. Spore maturation is progressive from the periphery inward. The two processes of cellular differentiation now proceed simultaneously and the formation of the sorocarp is completed by the transformation of all of the myxamoebae either into supportive cells, forming the sorophore, or into spores, forming the sorus."

Raper points out that after aggregation, there is no increase in the size or number of myxamoebae, but all further development consists entirely of the integration and subsequent differentiation of myxamoebae already present, which may be of wholly different spore origin and of initially equal potentialities. If myxamoebae are dissociated in the presence of bacteria, they return to the vegetative self-reproducing stage, though if no bacterial food is present, they re-aggregate and develop fruiting structures, whose pattern is constant, though the size is in proportion to the mass. Species thoroughly intermixed in the vegetative stage aggregate to separate and distinct centers; and though two species of *Dictyostelium* may initially enter the same fruiting organization, they later draw apart and form separate sorocarps, which are of a characteristic form for each species. "What is inherited is not a specific type of structure, but the ability of like but discrete and independent units to cooperate in the formation of such a structure."

The notion of catalyst modification, following upon differential diffusion which must develop when the pseudoplasmodium forms, could readily account for most of the observed facts. The segregation of cells of like species is observed with many organisms, and is dealt with in the paper of H. S. Jennings in this volume.

According to Topley, Wilson and Duncan^{135a} when a heterogeneous mixture of bacteria is agglutinated by a heterogeneous mixture of specific antisera, each cluster of bacteria is homogeneous. Apparently each kind of bacterium becomes coated by a layer of its own specific antibody, and the bacteria are so specifically conditioned that each kind forms a lattice or clump of identical unions through the adsorbed antibodies. A. Lazarow^{88a} isolated from finely dispersed liver by fractional ultracentrifugation, a submicroscopic particle containing glycogen. The particle has a sedimentation constant of $ca\ 4,000 \times 10^{-13}$, and appears to be an aggregate of smaller glycogen units held together by about 1 per cent. of protein, a coacervating agent which "seems to parallel the action of insulin, because insulin is known to lower blood sugar and facilitate glycogen storage in the liver." These two cases seem to be instances of *cohesive colloids*, mentioned in the first paper in this volume.

The question why the cells of the blastula tend to cohere was answered for some

cases by C. Herbst,⁷¹ who found that, while all of the salts in sea-water are important for the development of echinid eggs, if calcium was absent the cells of the developing embryo would fall apart, though they could live and develop further. An analogous role is played by calcium in soils, where calcium "humate" binds soil particles into the crumbly condition consonant with what agriculturists term good tilth. Alkali soils, besides being pasty and "sticky," tend to wash away. It may be that local, perhaps temporary, deficiency of calcium may be a factor in polyembryony, which seems to have occurred in the case of the Dionne quintuplets, and is common in some insects, especially wasps,¹³¹ where hundreds of individuals may thus arise from a single egg. Polyembryony in insects was first discovered by Paul Marchal (1898), and Prof. J. T. Patterson informs me that probably Marchal was the first to suggest that polyembryony in insects might be explained on the basis of Herbst's experiments with Ca-free sea water to separate the cells of sea-urchins. With the Texas armadillo which typically produces four identical quadruplets from a single egg, and the South American *Mulita* (*Dasyus hybridus*) in which one egg gives rise to from seven to twelve individuals of the same sex, some other explanation must be found, because the primordia of the embryos arise rather late in development. (See "Polyembryony in Animals," by J. T. Patterson, in *The Quarterly Review of Biology*, 2, 399-426 (1927)).

Because of their favored location relative to food supply and waste elimination, exterior cells tend to grow and to duplicate more rapidly than cells within the blastula. If the cells stick together, this demands an increase in the external cell surface of the blastula mass, and this can happen only in two ways: (1) by formation of a *diverticulum*, whereby the "skin" cells form a root-like projection; (2) by *invagination*, whereby the surface of the blastula bends inward to form a pocket or sheath. In animals the "skin" cells cohere so strongly to those within, that invagination occurs, leading to the formation of the gastrula. Thus, a hollow rubber ball immersed in gasoline superficially absorbs this rubber solvent, and the swelling surface tends to force an invagination at the weakest area.

With the formation of the gastrula a new set of physico-chemical conditions arises. The gastrula cavity may be regarded as a "bay" or inlet from the "ocean" of the milieu; and this bay will have, or will immediately develop, ionic and molecular concentrations different from those of the exterior "ocean" of the milieu. Cells facing the "bay," though originally "skin" cells, may be expected to react to their new situation by the adsorption and/or the elution of prosthetic groups or of specific catalyst modifiers; and modified catalysts mean a *change in chemical output of the cells*, which we finally recognize as *differentiation*. Furthermore, the interior cells of the gastrula and those in an intermediate position are differently situated relative to the exterior cells. There thus tend to develop three typical environmental zones, corresponding to the *ectoderm*, *mesoderm*, and *endoderm*. Just what may happen in and within these zones as a result of catalyst changes and/or catalyst formation enforced by ionic or concentration changes, or because of alteration in conditions governing catalysis, will vary in each case and will become increasingly more complicated as the growing structures evolve.

The viewpoint of biologists may be seen from the following quotations. H. S. Jennings states:⁷⁸ "At a certain time the egg of such a creature as a frog has become a mass of small cells. Under normal conditions, when we examine this mass, we can predict what part of the adult each part will produce. Cells here will produce the brain, there the sides of the eyes, here the ear, there the spinal chord, here parts of the skin. If we leave the egg to itself, these are indeed the parts that will be produced.

"But this is not because each cell can produce only that part and nothing else. . . . What happens is that from a certain spot on the egg—a recognizable spot—an organizing influence starts out, so that this spot is known as the organizer, or the

organization center. This organizing influence, whatever its nature, creeps from cell to cell, causing each cell to alter internally—through the interaction of its genes and cytoplasm—in such a way as to produce the structures of the embryo. Each cell that is reached later transforms in such a way as to fit the cells that have gone before—in such a way as to make the next proper part in the pattern of the body.”

Ross G. Harrison states:⁶⁴ “. . . the internal environment of a cell (is) the sum of all those factors with which it is in relation that lie within the organism but outside of the cell in question. Strictly speaking, a single cell has only an external environment. However, the germ cells that unite to form the fertilized egg do have in a certain sense an internal environment inside the body of the parent organism. When they are cast loose they cease for a time to have such an environment, and it is only after cleavage begins that the resulting cells acquire a new internal environment in their sister cells. For a short period this is the only internal factor that counts, there being as yet no general *milieu intérieur*. However, during this period, which in the vertebrate embryo includes segmentation, gastrulation, and neurulation, the most important differentiations occur. Later, after the establishment of a circulating medium and the primitive nerve paths, an internal environment of the ordinary sort is again present. . . .

“Since cellular differentiation takes place in the cytoplasm, we are concerned here more directly with this constituent of the cell, bearing in mind, however, that the cytoplasm is accompanied and ultimately controlled by the genic complex in the chromosomes. Since the latter is presumably the same* for all cells of the organism, differences between cells must arise through interaction between the constant genom and the locally variable cytoplasm, in which they ultimately become visible. . . .

“In the so-called mosaic eggs, *i.e.*, those with ‘precocious segregation,’ to use Lankester’s⁸³ term, local differentiation arises before cleavage and a minimum of modification in response to internal environmental factors is involved in subsequent development. In other eggs the protoplasm long remains labile with respect to its prospective differentiation, and in these many organs of the embryo develop only through the interaction between the cells producing them and other elements in the internal environment, *i.e.*, other cells and the internal medium. In such eggs local predetermination is reduced to a minimum. Their members in continuance† *are fashioned*, when as yet there is none of them.

“The most striking case of dependent differentiation is that of the central nervous system, which is formed in the outer layer of the embryo by reaction with the material underlying it, which is turned in during gastrulation. This material, because of its marked general effect upon the development of the embryo, has been termed the organizer by Spemann,¹²⁴ its discoverer. The material which is invaginated and which acts upon the overlying tissues forms the pharyngeal roof, head mesenchyme, axial musculature and notochord. . . .

“What it is that gives the organizer cells these properties, which are so effective as an internal environment to the overlying cells, and what the nature of the reaction in the surrounding tissues is, has not been ascertained. Spemann¹²⁵ himself experimented with organizer material the structure of which had been destroyed. Later Holtfreter⁷⁵ discovered that a great variety of animal tissues, both adult and embryonic, and from almost any phylum could, when placed in a blastocoel so that it ultimately came to lie under the ectoderm, stimulate the formation of a thickened area (neural plate) in the overlying tissue, which might fold over and close in as the neural tube does. Even pure chemical substances held in an agar matrix may

* We must here envisage the possibility that genes may be modified by specific substances, and that this modification may be persistently recurrent or even heritable. In this latter case the modification would be tantamount to a chemically induced mutation. J. A.

† Psalm 139.

have a similar effect. There is a difference, however, between the response to living normal organizing material and that to dead material, the former stimulating the formation of a complete neural plate and tube with normal regional differences, while the latter produces simply a thickened plate which may close to a tube without, however, showing such regional differentiation.

"Much effort has been spent to find out the nature of the chemical substance that produces these effects, and several different conclusions have been tentatively reached. The fact that certain embryonic tissues which have no organizing effect when living do so act when dead has led to the view that the substance responsible for the effect is free only in the active regions, but exists in a bound condition in other parts of the embryo. Needham, Waddington and co-workers^{141, 142, 25} have isolated sterol derivatives from the organizer and have found that synthetic sterols when applied in an agar matrix do induce the formation of neural-plate-like structures. Another fact that may be of significance is the occurrence of an intense carbohydrate metabolism in the organizer.^{28, 98, 147}

"Differences between the action of the natural organizer in its normal position and that of dead material and chemical substances may be due to the circumstance that the former is distributed in a gradient having different local concentrations. Another factor that may have some influence is the possible variation of the intensity of action with respect to time. A normal induction might be achieved only through the action of a living system, because this might require the action to start with a low intensity, increase to a maximum, and then taper off; or it might require several cycles of variation in intensity, which dead material could not afford. Regional differences in the reacting material must also be taken into consideration, as shown by the different respective reactions of presumptive head and trunk regions to similar implanted organizer material."¹²⁵

"What happens in the ectodermal cells that become transformed into neural plate is of much importance in any theory of organizer action, but it is almost entirely unknown. The neural plate contains relatively more water than the embryo as a whole⁵⁷ and it seems to be the inner portions of the neural plate cells that are the most swollen. We might assume, then, that the organizer produces a chemical change, which leads first to an orientation of particles that makes the cells columnar, followed by a greater hydration of the protein lattice localized in the basal halves of the cells. This would lead to the folding of the plate to form a groove and its ultimate closing into a tube. The changes underlying the process would thus be of a chemical and paracrystalline nature.

"It must also be borne in mind that the agencies effecting the differential changes in the central nervous system are heterogeneous in composition. Underlying the fore brain is the pharyngeal roof and some mesenchyme, and under the rest of the brain and spinal chord the notochord occupies the midline with the myotomes on each side. All of these factors are known to have a specific effect on the overlying neural plate.⁸⁹

"Since the word 'organizer' connotes a master regulator which creates the organization, and since there are in the course of development many actions of the same general character that could hardly be accorded such a role, it is perhaps more appropriate to use the word 'induction' to denote processes of this kind. Outside the area of the central nervous system there are many other ectodermal organs—balancer, gills, hypophysis, etc.—that are dependent upon other structures for their differentiation. Whether the ectodermal structures just referred to arise *in situ* through some localizing factor in the ectoderm itself, or whether they are produced by reaction with the underlying tissue is still uncertain in some cases. . . .

"In growth, as well as in differentiation, cells and cell groups are dependent upon one another. The proportions of an organism are acquired through the maintenance of the normal relative growth of its parts. Delicate adjustments are here necessary, but they are little understood, though known to be governed by both genetic and en-

vironmental factors. Rates of growth are specific, and each organ or part has its characteristic rate relative to that of the whole. Relative growth rates are susceptible to external and internal environmental influences, though in a much less degree than the general growth of the whole organism. . . .

"As stated above, there is almost no evidence that regions which are far apart affect one another during early stages of development, but as soon as the circulation and nervous connections develop, factors influencing differentiation become effective through these media."

Differentiation presents us with an endless variety of new substances and new structures, whose nature is mainly predetermined by the minute proportions of genic material in the zygote, and the tiny weight * but huge numbers of specific molecules in the zygote cytoplasm. It is maintained that these complicated, variable, but orderly procedures may be best understood as due to the directive activities of specific catalysts, genic and non-genic, the order, quantity and nature of whose chemical output is specifically varied, in time and place, by changes in them induced by specific catalyst modifiers, or established in them by prosthetic groups and carriers.

The basic modifier particles seem to exist in the inherited zygote cytoplasm, but other modifiers may come from the milieu or from food, or may be formed by the activity of the initially existing catalysts. Modification may involve total or partial inhibition of a catalyst, or else a promoter action, whereby certain potentialities of the catalyst are favored relative to other potentialities. Prosthetic groups and specific carrier substances formed by new or by modified catalysts, or set free by elution or desorption, may unite to form still other specific catalysts, whose chemical output underlies the specific structural pattern of the developing biont.

Associated with catalyst modification, and perhaps efficient in their own right as conditioning catalyst activities, are changes in the milieu immediately adjacent to a catalyst particle or surface. Such changes, especially in the absence of a circulatory system, would follow upon selective adsorption and differential diffusion of substances formed catalytically.

The catalytic view of life and of life processes accounts for the otherwise mysterious fact that from tiny spores or cells there arise, in regular order, such a host of different plant and animal structures. The initial "seed" contains merely the *determiners* of chemical changes that lead to the relatively huge mass of the individual. The Old Testament stressed *seed* rather than *blood*, genetics, rather than consanguinity, which is a consequence of catalysis.

Chemical Activators †

A great mass of evidence has accumulated to indicate that many important biological changes are directed, or powerfully influenced, by *exceedingly minute proportions* of highly specific substances, even though the *actual number of molecules* (or other particulate units) involved may be enormous. Some activators come from outside the organism, *e.g.*, vitamins from food, trace substances from the soil; others are formed within the organism, *e.g.*, auxins in plants, hormones and neurohumors in animals.

In 1921 Otto Loewi (Nobel Laureate) discovered ^{92a} that nerve impulses provoked by stimulation of the nerves leading to the heart, act in such a way that they release at the nerve ends chemical substances (acetylcholine or adrenaline), and

* H. J. Muller calculates ("Hors de la Nuit," Gallimard, Paris, 1938) that within the volume of half an aspirin tablet could be packed the sperm-heads required to produce two billion human beings.

† In discussing the activation of papain, J. S. Fruton and M. Bergmann [*J. Biol. Chem.*, 133, 153-156, (1940)] state: "The fact that the various activators may produce different specificities should play a significant role in the biological action of the intracellular enzymes."

that these substances are responsible for the changes in heart activity produced by the nerve impulses. Subsequently it was proven that this "chemical transmission" of nerve impulses to effector organs is generally valid within the peripheral nervous system. Torda and Wolff^{135b} report that there is an actual defect in the synthesis of acetylcholine in *myasthenia gravis*, a disease involving a slowly progressive and fatal fatigability and weakness of the muscles. Their investigation was suggested by the observation of Walker^{145a} that prostigmine, an inhibitor of cholinesterase, aids patients suffering from this disease, apparently by husbanding the lowered supply of acetylcholine.

Sir Henry H. Dale and collaborators found that each of the hundred (more or less) nervous impulses sent per second down a motor nerve fibril liberates at the nerve-muscle contact a cloud of molecules of acetylcholine, estimated by Langmuir to contain about 30,000 molecules. But these contraction-causing molecules are promptly de-esterified by an enzyme (cholinesterase), so that the gross muscular contraction is made up of a series of rapid "quantum" twitches, which may become evident as tremor if fatigue, age, or disease sufficiently lowers the twitch tempo.

Prof. George H. Parker¹⁰³ states that present evidence indicates that the terminal of a discharging neurone acts as a miniature gland, and produces a chemical substance able to excite the tips of the next neurone and thus initiate another impulse. Such chemical activators are called *neurohumors*, a term introduced by Henri Fredericq; and Parker would here include not only acetylcholine (Dale) and sympathin (Cannon), but also adrenalin and pituitary gland products known to activate animal effectors. Parker states:

"Neurohumors may act over distances of microscopic if not ultramicroscopic proportions or over large ranges in the animal body. Such substances, irrespective of their extent of spread, are in principle nervous activators and their grouping under one head, namely that of neurohumors, is fully justifiable. Some students of this subject would class all neurohumors as hormones; others would include under this heading only such as act over long distances, but this does not seem to me to be a matter of serious import. Neurohumors really act as hormones over shorter or longer ranges. The precise problem we have to face is not the classification of neurohumors, but the extent to which these substances actually exist."

Parker then discusses the nervous control of the color of fishes, going back to Pouchet (1876), who showed that if the integumentary nerves of a turbot are cut, the melanin granules in its melanophores undergo a *dispersion*, spreading out the color and darkening the skin. Parker further observes¹⁰⁴ that there are two classes of neurohumors: *hydrohumors*, soluble in water and therefore found in blood, lymph, etc., and *lipohumors*, soluble in lipoids, fats, oils, fat solvents, etc. He finds¹⁰⁵ that the color changes of catfishes are controlled by three chief neurohumors: intermedin from the pituitary gland; acetylcholine; and a concentrating neurohumor (probably adrenalin) from nerve fibers controlling, respectively, concentration and dispersion. Acetylcholine induces dispersion of melanophore pigment; adrenalin causes the reverse. Both are lipid-soluble, and acetylcholine, in its fatty retreat, may thereby be protected from destruction by cholinesterase; in fact, it accumulates to such an extent that its effects may persist after nerve action has ceased, and it may be extracted in measurable amounts from dark fish skins. "Thus the fatty or lipid substances in the animal body may serve as storage reservoirs for agents that may be of first consequence in the animal economy."

Francis B. Sumner¹²⁹ has discussed the quantitative changes in pigmentation resulting from visual stimuli in fishes and amphibia. We thus get an idea of how and why flat-fishes, chameleons, etc. change color in response to their surroundings. Measurable electric phenomena are associated with nerve functioning, and may be picked up from the heart (electrocardiograph), the brain (Berger rhythm), and in individual nerves (Adrian).⁴ D. Nachmansohn and collaborators^{56a, 98a} found

that at neuro junctions and synapses the distribution and high concentration of cholinesterase is such as to split within milliseconds amounts of acetyl choline which, if released at those foci, would be in sufficient concentration for a stimulating action. They also advance the view * that "acetyl choline metabolism is intrinsically connected with the electric changes occurring everywhere at the neuronal surface. Hence, it is only quantitatively more important at the synapse where the neuronal surface increases considerably due to the extensive end-arborisation. . . . Bio-electrical phenomena occur at surfaces. The localization of the enzyme at the surface and the high rate of acetyl choline metabolism are particularly pertinent in view of experiments in which a close parallelism could be established between the electromotive force of the action potential and the concentration of cholinesterase." This new concept reconciles the "electrical" and "chemical" theories of transmission of nerve impulses, for the main question at issue was whether or not transmission at the synapses was of a different kind than that in the axon.

It must be most strongly emphasized that no *one* mode of action can be invoked to explain the influence of all "trace" substances, especially with increasing complications in biont structure and organization. As indicated above, and as Svedberg found with the proteins (see p. 562), small amounts of specific substances may not only greatly affect the *degree of dispersion* (with corresponding results on kinetic activity and diffusibility, as pointed out on p. 554), but they may also greatly influence the *permeability of membranes or septa*. Thus moistening the gut with bile facilitates the passage of emulsified fats.^{95, 139} Many years ago R. Zsigmondy and Fr. N. Schulz¹⁵³ showed how a trace of egg albumen may permit colloidal gold to pass through Chamberland, Maassen, and Pukall filters, evidently because the filter pores preferentially adsorb a layer of albumen, thus preventing adsorption of gold particles which could clog the pores. Besides, the albumen exerts a deflocculating and protective action on the colloidal gold.

Another and most important function of trace substances is that they may serve as *catalysts*, or as *carriers* or *prosthetic groups for catalysts*. The direct catalytic results may not be recognizable in the often far-removed phenomena actually observed. For example, from 5 to 60 parts of copper in one hundred million of sea-water are essential for the transformation of a free-swimming oyster larva into a stationary "spat"; in brackish water a colloidal precipitate of copper oxychloride is formed which initiates the change about $4\frac{1}{2}$ minutes after ingestion.¹¹² A trace of copper seems essential to hemoglobin formation,⁶⁵ and Florida orange trees whose leaves had lost most of the green color (a condition known as "frenching") recovered when copper sulfate was added to the soil, their leaves yielding 4.6 times as much chlorophyll as the controls.¹⁰⁰ When one gram of $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ was added to 15,000 grams of Sassafras sandy loam soil (pH 7.1), tomatoes cultured in pots of the treated soil gave a pulp showing an increase in ascorbic acid (vitamin C) from 142 to 243 milligrams per liter.⁷²

Relative to differences in sex of plants,† Prof. W. F. Loehwing states:⁹² "More than a decade of research by the writer and his students upon dioecious species suggests that, among the most important physiological differences of the sexes, are the oxidation-reduction enzymes, marked quantitative if not qualitative differences in soluble carbohydrates, and qualitative contrasts in proteins. Mild hydrolysis of proteins in sexually differentiated hemp plants discloses arginine and lysine but no proline or histidine in staminate individuals, while pistillate plants are the exact converse. Tests for these amino acids in foliar tissues of vegetative plants without flower primordia enable one to forecast the eventual sex of the mature plant (Kiesel and Pachewitsch, 1938; Loehwing, 1939). Inception of staminate organs seems to be characterized by a preponderance of soluble sugars and presence of oxidase. Pis-

* *Science*, 1943, paper by Fulton and Nachmansohn.^{56a}

† Re sex in unicellular organisms see ^{124a}.

tillate loci have a preponderance of nitrogen and marked reductase activity (Loehwing, 1937; Stanfield, 1937). Though the foregoing appear to be significant physico-chemical differences between the sexes, we have not yet successfully distinguished cause and effect, nor have we the desired degree of voluntary control over carpo- and andro-genesis."

Since the chemical units represent mainly consequences of catalytic activity, it would appear that the differences described probably stem back to the original cellular biocatalysts.

In quite another field, we find remarkable evidence of chemical control in bees. In full season a queen bee may lay in excess of 2,000 eggs daily, more than her own weight. Unfertilized eggs give rise only to drones (males), but the fertilized eggs may give rise to workers (sexually immature females) or to queens: nutritional difference decides the outcome. Townsend and Lucas state:¹³⁶

"All female larvae are fed on royal jelly for the first 2-3 days after hatching and during this period their anatomical development is similar. Only the queen continues to receive this special diet. Any larva from a fertile egg, if given royal jelly throughout its larval period, develops sexually so that it becomes a perfect or true female bee, or what is called a queen; otherwise, the larva develops into a sexually immature worker. The queen is structurally much the same as the workers but with these important differences: the pollen-gathering apparatus remains undeveloped, the mouth parts and sting are modified, while the spermatheca and ovaries are highly developed."

These authors separated royal jelly into four fractions and found some evidence that the physiologically active material responsible for the sexual development of the queen bee, is in the ether-soluble fraction. More recently Pearson and Burgin¹⁰⁸ report that bee royal jelly is the richest known source of pantothenic acid, its 35.8 per cent dry substance containing from 378 to 618 (average, 511) mg of pantothenic acid per gram.

In discussing ants, G. H. Carpenter stated:³⁸

"One of the most interesting features of ant-societies is the dimorphism or polymorphism that may often be seen among the workers, the same species being represented by two or more forms. Thus the British 'wood-ant' (*Formica rufa*) has a smaller and a larger race of workers ('minor' and 'major' forms), while in *Ponera* we find a blind race of workers and another race provided with eyes, and in *Atta*, *Eciton* and other genera, four or five forms of workers are produced, the largest of which, with huge heads and elongate trenchant mandibles, are known as the 'soldier' caste. The development of such diversely formed insects as the offspring of the unmodified females which show none of their peculiarities, raises many points of difficulty for students of heredity. It is thought that the differences are, in part at least, due to differences in the nature of the food supplied to larvae, which are apparently all alike. But the ovaries of worker ants are in some cases sufficiently developed for the production of eggs, which may give rise parthenogenetically to male, queen or worker offspring."

Discussing the role of chemoreception in the ability of rattlesnakes to recognize ophidian enemies, C. M. Bogert²⁶ states that although rattlesnakes when confronted by man or by domesticated animals, normally assume a coiled defense attitude, with head raised ready to strike, immediately after exposure to ophiphagous king-snakes they react to contact and to visual stimuli only by assuming a characteristic "king-snake defense posture": head and tail flat on the ground, with the body arched to a high loop with which to strike a defensive blow. Rattlesnakes assumed this characteristic posture when placed in a receptacle that had previously held king-snakes, and also when a clean stick that had been rubbed on the back of a king-snake was held near. The activating substance is apparently taken up by the tongue and conveyed to Jacobson's organ, which contains olfactory cells; and the response was

evoked by visual or by contact stimuli as long as three hours after receipt of the original olfactory stimulus. Apparently some trace of a volatile substance powerfully conditions the behavior of the rattlesnake.

H. S. Raper and collaborators have shown¹¹⁴ that the enzyme tyrosinase catalyzes the conversion of tyrosine (an amino acid constituent of some proteins) into 3, 4-dihydroxyphenylalanine, called *dopa* for short. *Dopa* is then oxidized by the same enzyme to a red indole derivative which spontaneously changes to *melanin*, a pigment which gives hair and skin a dark brown or black color. Factors affecting the activation of the precursor of tyrosinase have been studied by J. H. Bodine and collaborators.²³ The pro-enzyme separates in the aqueous layer obtained by ultracentrifuging mashed grasshopper eggs, and is activated when added to the oily or lipid layer. Since chloroform, urethane, urea, heat and detergents (Duponol, Areosol) all produce the same final effect (active tyrosinase), Bodine states:

"The enzyme, tyrosinase, is protein in nature and as such shows all the characteristic properties of this chemical group of compounds. It, therefore, would seem logical to expect that activation may possibly be related to or dependent upon some physicochemical properties of this protein molecule and that the various activators employed bring about just such changes. Without adding unnecessary details in the way of experimental data, it may be stated that the activation of the melanin-producing enzyme in the present studies is thought to be brought about by the selective adsorption and orientation of the pro-enzyme molecules by the activating agents." Activation ceases to increase when the activator surface is occupied, either by pro-enzyme, or by another adsorbed protein.

The black spots on a Dalmatian dog appear where the local cells enable the melanin-producing process to occur, the remaining hairs being white. L. Earle Arnow¹⁷ found that in the presence of oxygen, tyrosine may be converted by ultraviolet light into *dopa*, which is then changed into melanin by an oxidase. Sun-tan appears to be so caused in some persons. A curious case of inhibition of skin pigment formation appeared in a large tannery, where a considerable number of workers (about 50 per cent, many of them negroes) developed white patches on their skins.¹¹⁷ Investigation showed that the rubber in some new gloves used to protect the workers' hands from an acid solution, had contained the monobenzyl ether of hydroquinone as an antioxidant, and that this substance also inhibits melanin formation; so that when the melanin originally present in the skin is absorbed or otherwise removed, the skin turns white (leukoderma). When the cause was removed the skin slowly returned to its normal shade, indicating that the pigment-forming mechanism was merely inhibited by the antioxidant, not destroyed. Normal skin color thus seems to represent a balance between pigment formation and removal.

E. L. Tatum and G. W. Beadle state:¹³³ "The development of eye color in *Drosophila* is known to be controlled by specific diffusible substances designated as v^+ and cn^+ hormones." By growing certain bacteria on an agar medium containing dead yeast, sugar, and *l*-tryptophane, "this bacterially produced v^+ hormone has now been obtained in a pure crystalline state," with "an activity of approximately 20,000,000 v units per gram when a solution is injected into vermilion brown test larvae."

An indication of how chemical control by trace substances may dominate fertility and thereby contribute an important factor to the course of evolution, is found in the Golden Rose strain of *Petunia*, which is completely self-sterile under natural conditions. Microscopic examination shows that its pollen tubes grow slowly, and that even before the most rapidly growing tubes reach half way down to the ovary, an abscission layer forms and blocks the way. Yasuda¹⁵¹ found that the placenta in the ovary of *Petunia violacea* secretes a "special substance" which diffuses into the style and completely inhibits pollen germination and tube formation. W. H. Eyster^{63a} found evidence that the ovarian secretion of the Golden Rose *Petunia* "which renders the plant self-sterile, can be transferred to other plants and renders them cross-sterile

with pollen from self-sterile plants." Golden Rose Petunia can be self-fertilized by two methods: (1) "If flower buds which are beginning to develop anthocyanin in the petals are opened and pollinated with pollen from fully opened flowers from the same plant, seed capsules containing viable seeds are produced"; similar results were found by Yasuda,¹⁵² who calls this homo-pollination; (2) by spraying the flowering plants with a solution of ten parts of α -naphthalene acetamide in one million parts of water.

"Flowers which are sprayed with this solution immediately before or shortly after they have been self-pollinated produce seed capsules filled with viable seeds in exactly the same way that normal self-fertile plants of other strains produce seeds. Obviously α -naphthalene acetamide neutralizes the effect of the ovarian secretion which diffuses into the style and inhibits or greatly retards the growth of the pollen tubes."

Dwarfism in certain plants (*e.g.*, maize, pea) has been shown to be due either to deficiency of auxin (growth hormone) or to its destruction by oxidative enzymes. J. van Overbeek¹⁰¹ further found that "laziness" in maize (a prostrate habit of growth) is consequent upon higher concentration of auxin in the upper part of the plant, whereas normally the reverse is true. He concludes: "It is thus evident that the lazy gene interferes with the auxin distribution in the stems which normally takes place under the influence of gravity."

While it has for some time been known that over about 1.5 parts per million of fluorine in drinking water generally produces a discoloration of the teeth known as "mottled enamel" (endemic dental fluorosis), recently Dr. H. Trendley Dean and collaborators^{41a} found that fluoride levels of less than 1.0 ppm were accompanied by a corresponding increase in dental caries. While the function of fluorine has not yet been established, it seems possible that the liberation of fluorine ions locally, by acid-producing bacteria would result in the inhibition or death of the bacteria if the fluorine concentration became sufficient before material attack on the tooth had resulted. The fluorine probably also gives the tooth a denser and less readily attacked structure. "Bone gives an x-ray diffraction pattern similar to that of the mineral apatite, the unit structure of which contains $\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2$. Various substitutions, such as $(\text{OH})^-$ for F^- and Mg^{+2} for Ca^{+2} , are known to occur in the apatite lattice without producing significant changes in the diffraction pattern."^{69a}

Wide use is made of ethylene gas (about 1 part per 1000 of air) to "color up" fruits and vegetables which must be shipped more or less "green" in order to stand handling and avoid spoilage. Bananas, melons, pineapples, persimmons, tomatoes, oranges, apples, pears, etc., are thus treated, the natural coloring processes being greatly accelerated. Celery may be thus blanched, and the hulls loosened from "stick-tight" walnuts. The diverse changes seem to be dependent upon initiating or facilitating specific enzymic changes.

Spraying apple trees with soluble thiocyanates, though it causes "spray burn" and a chlorotic condition of the leaves, tends to increase the red color of the fruit (blush) and to turn the green ground color toward yellow, both features desirable to consumers.⁴⁸ The red color is due to idaein, a glucoside which, on hydrolysis, yields cyanidin and galactose. There is some evidence that spraying apples with naphthaleneacetic acid and related compounds tends, with some varieties, to reduce the percentage of windfalls, apparently by firming the stems.^{74a}

D. W. Wooley has shown¹⁴⁹ that the mouse requires a new "vitamin" for normal growth and maintenance of hair. The facts indicate "that the mouse anti-alopecia factor is inositol or its derivatives. They suggest that inositol exists in liver in alkali-labile combination with a large molecule which renders the former non-dialyzable."

These scattering instances, which might be multiplied many times, illustrate how devious, various, and potent may be the effects of small amounts of substances, which,

until comparatively recent times, were generally considered "negligible" in reports of chemical analyses. Their effects are often expressed through catalysts.

DEVIATIONS FROM NORMALITY

Genic and Chromosomal Abnormalities, Natural and Induced

Darwin's great book, "The Origin of Species" (1859), is based on the notion that species were and are slowly and continuously changing, and that "natural selection," working upon the relation between these specific variations and the simultaneously changing environment, led to the "survival of the fittest" and the slow serial changes in plants and animals which we term "evolution."

In 1894 William Bateson in his book, "Materials for the Study of Variation,"* collected data which indicate that some variations are *discontinuous*, or to use an expression which followed the publication in 1901 of H. de Vries's "Mutation Theorie," that mutation is a *physiological event*. De Vries distinguished *mutations* from the common *variations*, found even in identical twins,^{93a} by the fact that mutations are transmissible to descendants and are therefore more permanent.

The term "mutation" should be, but is not now limited to changes in single genetic units (genes), which, according to our view, are the basic self-duplicating catalysts of the living unit (biont). The changed gene, commonly called a *mutant gene*, would lead (directly, or indirectly through the formation of catalysts, carriers or prosthetic groups) to alterations in the rate and/or the nature of chemical changes, that is, changes in the *chemism* of the biont, which may, in turn, lead to detectable consequences. In the case of *Drosophila melanogaster* it is estimated that about 2 or 3 per cent of the flies show detectable mutations, and of these about one-sixth are lethal. In view of the relatively huge molecular size and complicated structure of even a single gene, it is more surprising that precise self-duplication should occur so regularly, rather than that there should be occasional lapses, leading to changed effective catalyst surfaces. Such catalyst surface changes may follow (1) some form of "intramolecular change"; (2) the addition of or the subtraction of some physical unit (ion, atom, molecule, colloidal particle); (3) a change in position of a gene relative to some carrier substance in the gene-string, corresponding to the "position effect" well recognized by geneticists.

The causes of spontaneous or naturally occurring point mutations are obscure. Obviously, the gene must be sufficiently unstable to respond to such probable natural environmental impacts as radiation, activated atoms or molecules, or even the kinetic laws of chance. There is some evidence that mutations occur more frequently in the presence of increased natural radioactivity. Cosmic and solar radiations are possible but still unweighted factors, as are also the effects of such other natural physical agencies as heat, cold, desiccation and darkness. The effects of naturally occurring elements and compounds must also be considered. Most of us have observed, as did Faraday, the development of a violet color in white glass exposed to the sun, presumably caused by aggregation of manganese dioxide. Colorless gold ruby glass develops its red color when radiation (*e.g.*, by radium) causes its amicronic gold particles to aggregate to visible ultramicros. Commercially, the color in gold ruby glass is developed by a heating process, and the development and growth of the ultramicros can be followed in an ultramicroscope. (Zsigmondy)¹⁵³

The artificial production of mutations was initiated by the researches of H. J. Muller with x-rays. In two recent reviews,⁹⁸ one on induced mutation in *Drosophila*, Muller stated that at present radiation is the only known external agent capable of producing mutations in abundance and with predictable frequency. He

* "Bateson's call to a new study excited but little interest, and in a few years his book was to be found among the list of cheap remainders." Prof. R. C. Punnett, in "Background to Modern Science," p. 205 (The Macmillan Co., N. Y., and Cambridge Univ. Press, 1938).

pointed out that the effectiveness of radiation can be increased by the use of superior apparatus, but that even now it far exceeds usual calculations. For if a dose of 10,000 *r*-units acting for an hour* can give about 100 times as many lethals per X-chromosome in *Drosophila* spermatozoa as ordinarily occur in untreated material, we must remember that the "natural" mutations, used as a datum, represent the accumulation of a *Drosophila* generation covering two weeks or more—say 350 hours. The x-ray treatment has, then, increased the lethal mutations at least 35,000 times. To the lethals we must add the large number of detrimental and undetectable mutations, apart from the "desirable" ones sometimes found.

There is no room here to discuss the extensive evidence as to the nature of the physico-chemical changes involved in mutations induced by radiation. The following facts are now acceptable to geneticists: (1) "As to the mechanism of production of those radiation mutations which affect individual genes or narrowly circumscribed chromosome regions, the most important fact that has come to light is the dependence of any given mutation upon a change that was initiated in a single individual atom, by its ionization or other excitation." (Muller, *loc. cit.*, p. 151). (2) Structural changes occur in the chromosomes, because of breaks in the chromatin and a two-by-two fusion of the ends derived from different breaks. This cohesion of the loose ends suggests the presence of some substance which functions as a *cohesive colloid*,¹¹ and recalls the behavior of some bacteria (especially those with capsules), and of the two rubber latex layers on "self-sealing" envelopes, which cohere when lightly pressed together. The breaks may be gross, or else too minute to be microscopically demonstrable, and the phenomenon of "position effect" is evident. Thus, referring to the work of Panshin¹⁰² and of Dubinin and Sidoroff⁴⁶ Muller states: "In these works it was shown that, when a normal allele derived from a chromosome of normal structure is substituted by crossing over for a gene which, since the occurrence of a rearrangement in its vicinity, has functioned like a mutant gene, the substituted normal gene now takes on the properties that the apparently 'mutant' gene had, while, conversely, the removed 'mutant' gene reverts to normal functioning after its transference back into the chromosome of normal structure."

Reviewing seven years work with x-rays in the white-notch region of the X-chromosome of *Drosophila melanogaster*, M. Demerec and collaborators⁴⁴ conclude that there is an intimate relation between the various parts of the chromosome, the activity of a gene depending greatly upon its immediate environment. "The activity of a gene may be changed or suppressed by chromosomal rearrangements through which a foreign section of a chromosome is brought into contact with the gene."

To the writer, these findings indicate that the gene functions somewhat like a prosthetic group in an enzyme, for the activity of a prosthetic group depends upon the nature of its "carrier," and *vice versa*.¹⁴⁸

Muller believes that chromosomal breaks occur higher up in the "ascending hierarchy" of structure than peptide bonds. Rather than the simple plus-and-minus relationships suggested by Muller, the specificities involved in re-joining chromosomal fragments appear to involve pattern charges or mosaics of electronic areas, especially on close approach of units.

Mutations have been produced by ultraviolet radiation^{51, 90} as well as by x-rays, and M. Demerec and collaborators⁴⁴ report that neutrons are effective in inducing chromosomal rearrangements similar in frequency and general nature to those induced by x-rays. Mutation of bacteriophage has also been reported.³²

In reviewing a number of reports of gene mutations produced by such chemicals as iodine, copper sulfate, ammonia, potassium permanganate, mercuric chloride and lead salts, T. Dobzhansky⁴⁵ expresses the hope that the experiments will be repeated

* I am informed that gene or point mutations depend mainly upon the total quantity of radiation; chromosomal breaks on both quantity and time of radiation J. A.

and extended. Steinberg and Thom¹²⁷ have reported the production of mutations in fungi (*Aspergilli*) by the use of sodium nitrite in acid solution (i.e., nitrous acid) and of colchicine in the presence of excess of calcium carbonate. "The presence of high concentrations of *d*-lysine, the amino acid presumably affected by nitrite, brings about a reversal in mutation. Chemical conditions conducive to re-introduction of amino groups also bring about reverse mutation. Nevertheless, the precise nature of the underlying process is by no means certain as yet in the absence of cytological and analytical data. Nor is the formation of similar type mutants by colchicine particularly helpful to the interpretation of amino-group destruction. The mode of action of colchicine on fungi itself needs elucidation, since polyploidy need not necessarily or entirely enter into the observed responses of fungi."

The production of chromosome mutants by chemical means has been extensively demonstrated, principally by the use of colchicine, which by inhibiting spindle formation leads to cells with doubled chromosome number.^{15, 22, 31, 47, 66, 91, 93} Successful results have also been obtained with acenaphthene and β -indole acetic acid (hetero-auxin).

The transformation of Type II pneumococcus into Types I or III, mentioned previously may be a case of a chemically induced mutation, (even if we do not know the chemical nature of the effective mechanism), or else there is formation of a new and self-duplicating cytoplasmic catalyst, whose formation may in some cases be established by conditions favoring the union of existing carriers and prosthetic groups. Another case appears in the crown gall ("plant cancer") produced by inoculation of a host plant with the bacterium *Phytoplasma tumefaciens*, which was shown by E. F. Smith and collaborators¹²⁰ to develop true secondary tumors in sunflower plants several internodes away from the primary tumor. In confirming this work recently, P. R. White and A. C. Braun¹⁴⁵ found that the secondary tumors were generally sterile; and using recently developed techniques, they grew secondary tumor tissue *in vitro*. They found that it bred true; and the medium was bacteria-free, though capable of supporting a profuse growth of *Phytoplasma tumorfaciens*. The authors conclude that the affected tissues have undergone a drastic change, indicated (1) by the abnormal capacity to produce galls, and (2) by their abnormal growth habits *in vitro*. "That this change was originally brought about by some stimulus from the crown gall organism seems clear. That its maintenance is not dependent on the continued presence of the bacterium is equally clear."

Such results are understandable on the basis of chemically induced gene point or chromosomal mutation, or of the heritable modification of a gene or other cellular catalyst, by substances originally introduced by presence of the bacterium. In the case of modification, the modifying substance must be continually reproduced thereafter in the clone of cells, presumably by newly formed specific catalyst areas; or else the modifying particles originally introduced must form an autocatalytic (that is, self-duplicating) specific catalyst area or template. With modifying particles of complicated chemical structure, like many of the cancer-producing compounds, the latter effect seems more likely, unless there is a chemically induced mutation.

It seems possible that some viruses, entering the body as infective agents, may persist there and be transmitted to progeny, possibly forming a permanent addition to the self-duplicating units of the cytoplasm of body cells or of the body fluids. Mice experimentally inoculated with a non-fatal dose of choriomeningitis virus develop an immunity in 5 to 7 days and rapidly free themselves of demonstrable virus; but pregnant mice when inoculated seem to pass the virus on to their offspring, which develop after birth almost as normal mice, but continue to carry the virus and pass it on to their progeny.* In his Kober Lecture,† Dr. Charles Armstrong reported that a strain of choriomeningitis virus had been passed "in an unbroken series from an

* E. Taub, *J. Exp. Med.*, **68**, 229 (1938).

† *Military Surgeon*, **91**, 129-146 (1942).

infected mother through 11 generations of her offspring with no apparent tendency of the virus to weaken or disappear. It has also been observed by Haas,* that these congenitally infected mice are far more efficient transmitters of the disease to normal cage mates than are mice inoculated after birth." Here is another possible mechanism of inheritance, apart from the genes.

Abnormal Catalysts and Modifiers

We consider here only a few illustrative examples of the effects on the organism of small percentages of abnormal or strange catalysts and catalyst modifiers, disregarding the gross solvent or dispersing action which may be exerted by high local concentrations of such substances as phenol, acids, alkalies, etc. If the introduction into, or the formation within the body of foreign molecules results in harm to the organism, the material is generally classed as a poison; but here the quantitative factor is very important. Many poisons (*e.g.*, arsenic, strychnine) may be beneficial in small dosages; and essential trace elements (*e.g.*, iodine, copper) may be toxic if present in amounts which may still be considered small. The intense specificity of action of various drugs and poisons is the basis of their uses; and many of them, irrespective of the clinical effects or symptoms which they elicit, operate essentially by their influence upon biocatalyst systems, *e.g.*, cyanides, the "sulfa" drugs.†

Strange molecules are in some cases directly *eliminated* in the excretions (urine, feces, breath, sweat); in other cases they are *detoxicated* by combination with substances normally present, or by subjection to chemical change, presumably through the agency of specific catalysts, whereby they are oxidized, reduced, or otherwise converted into some harmless compound which may then be eliminated or destroyed. Many of the chemical detoxication processes appear to take place in the liver, that hotbed of potent biocatalysts. D. D. Van Slyke,¹³⁸ in discussing the physiology of the amino acids, points out that the liver may transform these compounds into urea, or into glucose, or into a storage form of protein. "The liver also appears to be the place where plasma fibrin and albumin are formed."

The mode of detoxication varies with the changing catalytic and chemical structure of the animal. Thus phenylacetic acid and its homolog benzoic acid, are combined, in fowls, with ornithine. All mammals combine benzoic acid with glycine and eliminate it as hippuric acid; and the lower animals, including monkeys, combine phenylacetic acid with glycine, eliminating it as phenaceturic acid. But Sherwin¹¹⁸ found that man couples this latter poison with glutamine and eliminates it as phenylacetylglutamine. Experimenting on the chimpanzee, F. W. Power¹¹⁰ found that this "man-ape" eliminates phenylacetic acid in the same manner as does man. Here too, as in the biochemistry of muscle, there is a definite relationship between chemical mechanisms and the position of the organism in the evolutionary or taxonomic scale.

Disease

The influence of heredity factors on individual health and behavior was recognized in the four "temperaments" of the ancients: (1) sanguine, (2) phlegmatic, (3) bilious or choleric, (4) melancholic. Later on medical men spoke of "diathesis," which generally meant a predisposition to some disease, *e.g.*, gout. Even Aesculapius had described the structural type of individuals who were predisposed to tuberculosis.

In his recent book on medical genetics, L. H. Snyder¹²³ points out that the familiar 3 : 1 ratio of Mendel no longer covers the major portion of the field of heredity, for geneticists have demonstrated varied types of heredity transmission—dominant, recessive and blending—as well as varied relationships and behaviors of

* V. H. Haas, *Pub. Health Rep.*, 56, 285 (1941).

† See, *e.g.*, "The Interaction of Drugs and Cell Catalysts," by Prof. Frederick Bernheim (Burgess Pub. Co., Minneapolis, 1942).

genes, *e.g.*, autosomal, sex-linked, sex-influenced, lethal, epistatic and combined genes as seen in multiple alleles and multiple factors. As an example of epistasis,* it has been observed that in rabbits and mice the factor for gray, if present, prevents the development of the factors for black and chocolate. Many traits and abnormalities are transmitted by heredity, *e.g.*, polydactylism (supernumerary digits on hands or feet), syndactylism (webbed fingers or toes). Strains of Dalmatian dogs have been selected and bred which take definite positions—some close to the horse, some beneath the wagon, and some behind it.⁸²

Among the many diseases transmitted by heredity are allergies, hemophilia, endemic goiter, and a variety of nervous conditions including insanity and Huntington's chorea.¹⁴⁰ The violent convulsive movements in this last-named disease generally appear in adults and follow degenerative changes of ganglion cells of the frontal cortex and of the cordate nucleus and putamen. Davenport⁴⁰ states that traits known to have a chemical basis have the cleanest-cut genetics, *e.g.*, blood groups, cretinism (thyroid deficiency), amurotic family idiocy (a recessive associated with the storage of phosphatides).

A striking instance of inherited metabolic error is the rather rare alkaptonuria (recessive) first described by von Boedecker,²⁴ and recently observed in an American Negro family.¹ In these cases the urine contains homogentisic acid, shown by Wolkow and Baumann¹⁴⁸ to be 2, 5-dihydroxyphenyl acetic acid, which is labile and oxidizes, turning the urine black. Apart from occasional blackening of cartilage (ochronosis) no other trouble is evident. Homogentisic acid apparently arises from the blocking, at this stage, of the normal oxidation of tyrosine and phenylalanine (constituents of many proteins), for normal persons fully oxidize this acid and perfusion through normal liver converts it into acetoacetic acid. Dakin³⁹ showed that alkaptonuria patients can fully catabolize *p*-methylphenylalanine and *p*-methoxyalanine, which cannot form quinoid derivatives; he believes that in these cases inability to catabolize homogentisic acid is associated with increased formation of the quinoid intermediate from which it is derived.

Davenport⁴⁰ states: "The relation between the somatic expression of a trait and its chemical basis may be remote. Thus hardness of hearing seems to depend on a defect in calcium metabolism such as causes abnormal bone formation at the oval window of the inner ear and simultaneously in other parts of the temporal bone.† In the latter case there is reason for concluding that the result depends on a dominant factor in an autosome which modifies the reaction of the mesenchyme and a sex-linked gene which perhaps affects calcium metabolism. Indeed it seems probable that in time chemical errors in the body may throw light upon the chemical processes of development.

"The fact that so many mutations have a known chemical basis and that development is, indeed a biochemical process, raises the question whether all mutations have not, and leads us to seek the chemical basis of any defect. As the chemical bases of mutations are discovered the mutations may well be classified on a chemical basis rather than a morphological."

An instance of the importance of environmental conditions in aiding to establish the effects of stranger molecules appears in the photosensitization of organisms. In 1897, O. Raab observed that small amounts of acridine, while without effect in the dark, exerted a lethal action on paramecia in the presence of light. Later, similar effects were seen with eosine, chlorophyll, etc. In a recent book on this subject, H. F. Blum^{22a} describes a number of diseases which develop in grazing animals (sheep, horses, cattle) when they eat certain plants, *e.g.*, fagopyrism, due to buckwheat (*Polygonum fagopyrum*); hypericism, due to St. Johnswort (genus

* Epistasis, in Mendelian inheritance, means "the expression of one character to the exclusion of another not of the same allelomorphic pair" ("Standard Dictionary").

† There are other forms of deafness than otosclerosis. J. A.

Hypericum); geeldikkop ("yellow thick head") caused by the South African plant *Tribulus*, sometimes called "devil's weed." In geeldikkop the active material seems to cause liver injury and occlusion of bile, with jaundice, leading to retention of phyloerythrin (a chlorophyll derivative). This substance, accumulating in the skin, makes the animal light-sensitive and results in edema of the head and other places exposed to light.

Blum believes that the only way to account for all the evidence is to assume that when a quantum of light strikes a dye unit in a substrate-dye combination, the dye portion is activated and thereupon transfers its activation to the substrate, which then reacts with oxygen and injures cell structure. Having found that proteins which form the solid structure of the cell are fibrous, Prof. A. Szent-Györgyi¹³² (Nobel Laureate) advanced the idea that activated electrons may travel some distance within their own specific band or energy level, "and can fall to a lower level and give off energy only at a place where they can do work (e.g., a synthesis), analogous to the ZnS phosphors of Riehl,"¹¹⁶ where "the electron, raised to a higher level by a collision with an α particle, can travel relatively long distances and will fall back to a lower level, giving up its energy, where it meets with a Cu atom present as an impurity."

While agreeing with the importance of Szent-Györgyi's view that there exists a mechanism permitting the transfer of the energy of absorbed light or chemical reaction, without degradation or dispersion, for chemical reactions in relatively distant portions of the system, E. W. and F. H. Pike^{109a} state: "... the whole chemical and physical behavior of proteins and other biochemical substances would suggest a van der Waals' binding, which does not have extended electron states, rather than the electron band binding typical of salt or the diamond. It is well known that neutral or excited atoms, molecules, or free radicals may be adsorbed on solid or liquid surfaces as a mobile two-dimensional gas. Such excited mobile entities constitute a second possible mechanism for the effects which Prof. Szent-Györgyi discusses. Others are known, and it would be a daring biologist who would suggest that there are no more undiscovered mechanisms."

Cancer *

Cancer has been defined diagnostically as a growth of cells which is progressive and invades healthy tissue; but a much clearer understanding of the basic cause of this protean group of diseases is to be had if we descend to the catalytic level. For catalysts (genes, enzymes, symbionts) dominate the chemical and physico-chemical changes which underlie morphology and physiological function.

The development of cancers in man and in animals has long been associated with exposure to certain influences and, more recently, to certain definite chemical substances. Thus the natives of Kashmir who carry a charcoal brazier (*kangri*) about their waists and often suffer burns, are prone to develop *kangri* cancer. The British surgeon Percivall Pott observed that chimney-sweeps frequently develop scrotal cancers, and later it was noted that cotton spinners exposed to oils and workers in aniline factories † have a high incidence of cancer. Seamen exposed to tar and to insolation, as well as sufferers from "x-ray burns" are likely to develop cancers, although now x-rays of certain wave length and intensity are helpful in attacking the disease.

In 1915 Yamagawa and Ichikawa¹⁵⁰ were able to produce cancers in the ears of rabbits by continued application of certain tars. In the valuable book of Louis F. Fieser⁵⁴ there is reviewed the fascinating story of the team-work of chemists,

* See paper by Leo Loeb in this volume.

† On dehydrogenation and condensation two molecules of β -naphthylamine yield 3, 4, 5, 6-dibenzcarbazole, which causes proliferation of the gall ducts in mice. If given orally or subcutaneously α -amidoazotoluene produces liver and bladder cancers.

physicists, physiologists and others, describing the isolation from carcinogenic tar of a previously unknown but strongly active hydrocarbon, 3, 4-benzpyrene, present to the extent of about 0.003 per cent. After identification, this substance was synthesized; and the synthetic substance was found to be identical in its action with that extracted from tar. After high-boiling tar fractions proved to be non-carcinogenic, Hieger⁷⁸ observed that active tars and oils gave a characteristic fluorescence spectrum, with bands at 4,000, 4180, and 4400 Å. It was then found that 1, 2-benzanthracene gave similar bands, and J. W. Cook prepared a large number of allied compounds, of which 1, 2, 5, 6-dibenzanthracene proved to be actively carcinogenic—the first pure compound of known structure to be thus identified. Finally, in 1933, Cook, Hewett and Hieger³⁵ extracted from about two tons of tar the very small percentage of 3, 4-benzpyrene, which produces epitheliomas in mice in about 5.7 months on application of dilute benzene solutions, whereas 1, 2, 5, 6-dibenzanthracene takes about 8 months to produce this effect. Later it was found that methylcholanthrene, closely related to certain sex hormones and first made by degrading desoxycholic acid (a bile constituent), is still more potent, acting in about 5 months. These substances may cause cancers to develop in various tissues, *e.g.*, epitheliomas when applied to the skin, sarcomas when injected subcutaneously. Fieser states (*lib. cit.*, p. 86):

"While proof is entirely lacking, it appears possible that many forms of cancer may originate in the metabolic production of methylcholanthrene or related substances from the bile acids, or perhaps from sterols or sex hormones, of the body. . . . Entirely unknown is the mechanism whereby certain hydrocarbons start normal cells on a career of malignancy. If a chemical reaction is involved, the nature of the change is entirely obscure. . . . Possibly the molecular dimensions and the surface activity of the substances are as important as their chemical characteristics." (p. 92).

Dr. Charles Huggins (Dept. of Surgery, Univ. of Chicago) has just reported* that "it is possible by reducing the amount or the activity of circulating androgens to control, more or less but often extensively, far advanced prostatic cancer in large numbers of patients. In this special case, androgen control seriously disturbs the enzyme mosaic of the cancer cells at least with respect to the important energy producing protein-catalysts, the phosphatases. As a contribution to the problem of cancer treatment, it is well to emphasize that any interference with an important enzyme system of a cell, normal or malignant, will cause in that cell a decrease of size and function."

The common denominator in all cancer cells, however they may first be formed or appear, is that their changed properties and behavior are heritable, even in tissue cultures. These changes stem back to a changed chemism, which, in turn, is dominated by heritable changes in biocatalysts (genes, enzymes)† whose catalytic specificities may not even exist in the smaller chemical entities into which they may be resolved or broken down when subjected to chemical examination and analysis.

As far back as 1902 Boveri²⁷ suggested that cancer might be due to genetic factors, and since 1929 J. Alexander^{8, 12} has repeatedly advanced the view that cancer is consequent upon heritable gene mutations and/or gene or other catalyst modifications, of such nature that the specifically effective abnormal catalyst surfaces are heritably reproduced. While specific catalyst modifiers, carriers, or prosthetic groups, may themselves be reproduced (that is, produced catalytically), there is no evidence and little probability that a cancer cell primarily brought into existence by exposure to 3, 4-benzpyrene, methylcholanthrene, or 1, 2, 5, 6-dibenzanthracene, will continue to reproduce these specific and complicated compounds. What must be

* *Science*, 97, 541-44 (1943).

† The well-known chicken sarcoma of Rous follows invasion of the cells by a specific virus; but it is not known whether this virus or some of its by-products act as modifiers, prosthetic groups, carriers, or catalysts.

heritably reproduced are the *specific catalyst areas* which enforce the formation of substances that determine cancer. It is the *diagnostic or clinical consequences* and not any basic physico-chemical difference of process which distinguish the heritable changes in cancer cells from those other heritable changes in cells which underlie differentiation and also evolution, which latter we shall next briefly consider.

PHYSICO-CHEMICAL MECHANISMS IN EVOLUTION

In the popular mind at least, the unanimity of scientific opinion in affirmation of the evolutionary origin of new species of plants and animals is beclouded by divergencies of opinion as to the underlying causal factors and their relative importance. The notion that all the species first created, according to the Biblical Chronology of Archbishop John Usher,* in the year 4004 B.C., have persisted unchanged since then, was founded upon interpretations of Holy Writ by certain theologians, and is still maintained by some individuals and sects, as is also the notion that the earth is flat. The records of the rocks, read by geologists, paleontologists, and other scientists, give ample evidence of the immense age of the earth and demonstrate the reality of an "*échelle des êtres*" extending back for millions of years; and observations of biologists on the variations developing in plants and animals, both under domestication and in a state of nature, show that these variations are so wide and so numerous as to offer ample scope, *if and when they are heritable*, for the operation of natural selection (Darwin) or the survival of the fittest (Spencer) in the formation and establishment of new species.

"The term *species* corresponds to what is popularly called one 'kind of organism'; generally speaking, a species may be said to consist of individuals all of which interbreed freely under natural conditions. No very exact definition, however, can be given to this or any of the other categories of classification; they are all essentially arbitrary groups." (Charles R. Plunkett¹¹¹).

Because of differences in *habit* (psychological and reproductive isolation) or of *habitat* (geographical and ecological isolation), some species (certain rodents) that *can* interbreed rarely do so under natural conditions, and may become cross-sterile later because of small divergent heritable changes.† Artificial insemination has produced the tiglon (a cross of lion and tiger). Breeders produce the hinny (stallion × she-ass), and the well-known mule (jackass × mare), which is generally sterile, though a few cases of fertility in mules have been reported. But the crossing of species may fail under natural conditions because the offspring is non-viable or is sterile. Non-viability may appear at any time, from the stage of fertilization (if this occurs) to an advanced stage of development; and all intermediate stages exist between complete interspecific fertility and complete interspecific sterility, which is sometimes the result of non-development of the gonads, but which may result in much simpler fashion. Thus the sterility of the Golden Rose Petunia (p. 582) is consequent upon the action of some substance which prevents the pollen tubes from reaching the ovary; and the fig trees imported into California failed to produce fruit until there was also imported a certain insect which accomplishes fertilization of the flower. Many plants are dependent upon specific kinds of insects for fertilization.

What factors underlie sterility, which ordinarily acts as a barrier between species? The proximate causes may not, of themselves, give a satisfactory answer.

* According to Usher's "Annales" (1560), the Creation began on Sunday, Oct. 23rd, with the creation of light and the Angels, and ended at sundown of Friday, Oct. 28th, 4004 B.C., after the creation of the animals and of man. Saturday was thus the first Sabbath, meaning in Hebrew *rest from labor*. It is interesting to note that the relative order in which conditions and organisms appear in the Biblical story correspond in the main to what is scientifically accepted.

† Dobzhansky, ref. 45, p. 257, gives a more detailed discussion of physiological isolation mechanisms.

Thus a cross between a diploid and a tetraploid race yields the usually sterile triploids, and sterility may also follow other chromosomal aberrations, *e.g.*, some translocations. If we follow the effects of chromosomal aberrations to a lower level of material organization, it seems reasonable to believe that they may lead to changes in the catalytic output, *e.g.*, by action of "position effect" or by upset in "genic balance," with the result that new substances may appear, or else that old substances may be formed in larger proportions and thereby reach new places and exert new effects in the developing biont. The formation of even traces of a new substance that could affect protein aggregation or serve as the carrier or as the prosthetic group for enzymes having a new functional ambit, might initiate far-reaching changes in chemical output and in physical and physio-chemical structures and function. Point mutations can produce similar results, and so may changes in, or the formation of other biocatalysts, if there exists a mechanism for their heredity continuance.

This raises the question as to whether there may not be some non-genic form of inheritance, apart from the well established genic inheritance.

In his "Philosophie Zoologique," first published in 1809, J. B. Lamarck enunciated two "laws" which may be summarized as follows: (1) Frequent and continued use of any organ gradually develops it, enlarges it, and gives it a power proportionate to the duration of its use. Disuse has the contrary effect. (2) Whatever nature has allowed individuals to acquire or to lose by influence of conditions to which their race has long been exposed, nature preserves in the generation of new individuals, providing that the acquired changes are common to both sexes, or to those who have produced the new individuals.

The sweeping generality of these "laws" was not supported by the fantastic explanation that Lamarck gave for the development of horns in cattle and of antlers in deer, which he attributed to an "interior sentiment in their fits of anger, which directs the fluids more strongly to that part of their heads." This explains certain objections to Lamarckism, expressed in the amusing lines of James Russell Lowell ("The Biglow Papers," First Series, No. 4, line 31, *et seq.*):

"Some flossifers think that a fakkilty's granted
The minnit it's proved to be thoroughly wanted. . . .
Ez, fer instance, thet rubber-trees fust begun bearin'
Wen p'litikle consunnces came into wearin'—
Thet the fears of a monkey, whose holt chanced to fail,
Drowed the vertibry out to a prehensile tail."

As knowledge of the physical basis of heredity developed, it became evident that the chromosomes are the main vehicle of heredity; and they are by many believed to be the only vehicle. On the other hand, paleontologists continue to point to the definite though fragmentary fossil record, which to them indicates that results simulating the inheritance of acquired characteristics commonly occurred over the immense periods of the geological past. But they suggest no causal mechanism, and as Thistleton Dyer said in his address to the British Association for the Advancement of Science (Section D) at Bath in 1888: "Science will always prefer a material *modus operandi* to anything so vague as a tendency." On the other hand, Prof. E. G. Conklin stated:^{34a} "The classic argument of the Weismannians was that *we can conceive of no mechanism* by means of which somatic changes can be carried back into the germ cells, and therefore there is no such mechanism. Now the fallacy of this argument is obvious; even if we could conceive of no suitable mechanism for this purpose, this does not preclude the existence of such a mechanism." With the failure of repeated attempts to bring satisfactory experimental proofs of the in-

heritance of acquired characteristics, this view became and still remains *tabu* in biological texts and teachings.*

Nevertheless, the view had its sponsors, among whom was J. T. Cunningham. He suggested³⁸ that the mechanism whereby "modifications produced in the soma by external stimuli could affect the determinants in the gametes in such a way that the modifications would be inherited," involved the action of hormones, that is, "special chemical compounds (which) take the place of the imaginary gemmules of Darwin's theory of pangenesis of the 'constitutional units' of Spencer." Stressing the fact that the theory of the heredity of somatic modifications is not in opposition to the mutation theory, Cunningham states: "there are two kinds of variation in evolution, one somatic and due to external stimuli, acting either directly on passive tissue or indirectly through function, and the other gametogenic and due to changes in the chromosomes of the gametes which are spontaneous and not in any way due to modifications of the soma. Adaptations are due to somatogenic modifications, non-adaptive diagnostic characters to gametogenic mutations. It is a mistake to attempt to explain all the results of evolution by a single principle." (p. 241).

In a recent paper entitled "Environmental Transformation of Bacteria," Prof. W. H. Manwaring^{93a} stated: "These studies suggest a Lamarckian rather than a Darwinian world, or at least a world in which both Lamarckian and Darwinian evolutionary mechanics are operative." Henry Fairfield Osborn^{100a} stated in the third of a series of addresses on the origin of species, that the theories of Buffon,† Lamarck and Darwin, usually regarded as contradictory, are really complementary, for they all turn on the question of inheritance or transmission of individual adaptation, which may furnish the key to evolution. "On the affirmative side paleontology proves that in the long run of geologic or secular time both Buffon and Lamarck, as well as Darwin, were right in their main conceptions: organs starved by unfriendly environment finally disappear; organs which do not pay their way or are starved by disuse slowly drop out of the germ-plasm; vitally essential organs are either absolutely stable or progressive. Why not therefore concede the truth of the great conceptions of Buffon and Lamarck, even if immediate inheritance by the germ is disproved in the great majority of cases? Why not concede the still greater conception of Darwin, misled as he was as to time by the marvelously rapid evolution of the germ-plasm witnessed in artificial selection?"

Catalyst modification, which may in turn lead to the formation of new carriers or new prosthetic groups, offers a simple but potent mechanism whereby non-genic as well as genic changes may be heritably transmitted. This does not mean that any and all non-genic changes are necessarily heritable; but the unequivocal demonstration of a single case of heritable non-genic catalyst change would compel us to regard the principle as demonstrated, or, to use a legal analogy, as permissive though not mandatory in function. In fact, nature represents a balance among various factors

* In the preface of his book "Germ Plasm" (1893), Prof. A. Weismann wrote: "I finally became convinced that an epigenic development is an impossibility. Moreover, I found an actual proof of the reality of evolution." Epigenesis is the theory that the germ is created by union of the fecundating principles of the male and female, and that it does not pre-exist in the ovum or spermatozoon; and in this quotation the word *evolution* had its original biological meaning, *i.e.*, an unfolding of the germ that pre-exists in the parent, and contains all the parts of the fully formed organism in minute form, somewhat like the homunculus of Paracelsus.

According to Weismann, *idants*, the main divisions of the germ plasm, are made up of *ids*; *ids*, of *determinants*; determinants, of "*biophores*." A certain portion of the immortal germ plasm is told off to carry on the unaltered heredity, while the rest is sorted out to direct differentiation and development of the somatoplasm. Weismann's view that the germ plasm could not be changed by the somatoplasm was supported by the failure of various experimental attempts to demonstrate the inheritance of acquired characteristics.

† Direct action of environment.

and therefore a compromise of tendencies. Once a *modus operandi* is established, a tendency ceases to be vague even in the many cases where it is not obviously realized. Many demonstrable facts of astronomy do not create a demand for their experimental duplication, because their magnitude transcends our ability to establish conditions that could result, for example, in a solar system or a galaxy. Although the exceedingly tiny atoms, molecules and ultimate biological units are apparently within our grasp, we often lack both the knowledge and the ability to control the infinitude of their structures, relations and behaviors. Furthermore, most experiments in the biological field are judged at the diagnostic level; that is, they involve the reading of end results at higher structural levels rather than observations of the behaviors of the basic units or mechanisms. The behaviors are rationally deduced or mathematically calculated under conventional assumptions.

Definite chemical substances demonstrably produce heritable changes in bionts. With colchicine the changes are attributed to heritable increase in chromosome number. With some carcinogenic substances the heritable changes seem to be at least in part nuclear. In the transformation of bacteria and in tissue cultures of plant and animal cancers, gene changes are possible though not demonstrated.

Knight and Stanley⁸⁴ found a marked difference between the amino acid content of ordinary tobacco mosaic virus and the Holmes rib grass strain. Unless it can be shown that still smaller units produce "virus," or that viruses act as catalysts to form other substances than themselves, these figures reflect a chemical difference in the virus substance, which Knight and Stanley consider a mutation. The relation of

| Ordinary Tobacco Mosaic Virus..... | 3.8 | 4.5 | 6.0 |
| Holmes Rib Grass Strain..... | 6.4 | 3.5 | 4.3 |

the activity of tobacco mosaic virus to the presence and cogency of certain chemical groups or structures is shown by the conclusions of Anson and Stanley:^{16a} Tobacco mosaic virus whose SH groups have been oxidized beyond the S-S stage by iodine, but whose tyrosine groups have not been converted into di-iodotyrosine groups, still retains its normal biological activity against tobacco plants; but inactivation follows conversion of the tyrosine into di-iodotyrosine. Biological activity fluctuates with chemical changes in biocatalysts.

Considering the interaction of cytoplasm and chromosomes in genetics and in development, Prof. H. S. Jennings⁷⁹ points out that these two cellular divisions "are not separate in fact and in substance, though they are often kept isolated in concept—to the great detriment of sound understanding. There is a continual cycle of interchange between them, a transformation of material from one into the other . . . the cytoplasm is not merely passive; it actively determines what shall happen in the chromosomes. . . . Every cell retains all the chromosomal materials, but which of these materials comes into action in each cell depends upon what cytoplasm is there present, as well as upon the conditions under which the reactions occur. . . ." Jennings then lists three classes of heritable modifications in protozoa: (1) degenerate changes induced by unfavorable conditions acting for many generations; (2) acclimatization to high and low temperatures or to injurious concentrations of chemicals (As, Sb, quinine, methylene blue and various organic substances); and (3) alterations in form and structure, not involved in (1) and (2), which may be retained for hundreds of generations.^{80a} Referring to the observations of De Garis⁴² on *Paramecium caudata* through a long series of asexual generations, Jennings states: "At every succeeding fission the original cytoplasm is diluted to one-half, so that after ten generations it is diluted to less than $\frac{1}{1000}$ part, the remainder being new

cytoplasm produced by growth. Yet after ten generations the nature of the original cytoplasm still has a marked effect on size. The original cytoplasm seemingly must therefore have to some extent the power of reproducing itself in its distinctive nature, at the time that growth occurs. In this respect it partakes of the character of a gene or genetic material, in that it affects the character of the individuals and reproduces itself in some degree true to type. But in time it is made over by the nucleus."

When a race of *Paramecium* averaging in length 198 μ was mated with another true-breeding race averaging 73 μ , the influence of the cytoplasm was evident in one experiment for 36 generations, for only then did the descendants reach about the same size, although they all had the same chromosomal content. Referring to experiments of Jollos^{80a} indicating that such environmental modifications as acclimatization (see above) are inherited for as much as 800 generations, Jennings says: "If they are merely modifications of the cytoplasm one might anticipate that long before so many generations had passed the cytoplasm would have been made over by the nucleus, and its modifications would have disappeared. Yet we do not know that the time required for the nucleus to dominate the cytoplasm would be subject to the same limits in all cases. The question whether inherited environmental modifications are exclusively cytoplasmic, or whether they affect the nucleus, the chromosomes, must be left open for the present."

If persistent heritable nuclear and cytoplasmic changes were the usual, rather than the unusual fact, nature would present a confusion of bionts. And among the relatively few heritable changes of all kinds that actually occur, most are either detrimental or else represent no outstanding advantage to the inheritors. On the other hand, nature is continually conducting a vast multitude of experiments, over endless eons, and under an enormous range of ever-changing conditions. Even where a newly developed individual is of a type possessing the potentiality of persisting and/or dominating under conditions existing at the time of its emergence, it would have but slight chance of surviving and establishing a new strain in the face of established forms and predators. We must remember, however, that each new form of biont established adds to the amount and variety of chemical substances available to other bionts, either through the products of its metabolism or through its own body, living or dead. In general, each higher form of life depends upon simpler forms to supply it with essential molecules, which are molded into its own species-specificity by the analytic and synthetic action of its own catalysts. Thus man depends on simpler forms of life for his supply of the principal food molecules (fats, carbohydrates, proteins) and also for many essential trace substances (vitamins) some of which supply carriers or prosthetic groups for vital catalysts. Therefore food has an important evolutionary aspect⁸ and there is truth in the French aphorism: "Rien n'est la proie de la mort; tout est la proie de la vie."

Geological and meteorological factors have also played an important role in evolution, for they determine where and under what conditions bionts must live. Thus it is believed that great outbursts of volcanic activity during the Upper Cretaceous period kept the atmosphere so filled with colloidal dust that glaciation resulted through failure of normal solar heat to reach the earth's surface. Volcanic dust and lava also establish new chemical and physical soil conditions. A subtle, potent, but obscure evolutionary factor lies in the exposure of bionts to unaccustomed chemical elements or compounds by virtue of soil changes, and because of their enforced change of habitat and food. Highly specialized dinosaurs are supposed to have perished upon drying up of the swamps which furnished them with food and shelter; but some bionts (*e.g.*, brachiopods) survived over geological epochs apparently because they lived in relatively stable ocean zones, while others (*e.g.*, ants, cockroaches) seem to have survived because of their adaptability. Great earth changes,

over long periods of time, appear to have left some heritable impress upon surviving bionts.

How can heritable factors, apart from genic or chromosomal changes, enter into and affect the germ cells which carry heredity?

It is reasonable to believe that the cytoplasm of germ cells, like that of other cells, tends to receive an average supply of molecular flotsam and jetsam, that is, of all particulate units which are carried throughout the biont by circulation and diffusion, and that among these molecular or near-molecular units are those that determine, or aid in determining, differentiation. Apart from other evidence, the fact that some differentiated cells can breed true in tissue culture warrants belief that specific tissues or organs contribute to the molecular melée in the organism units capable of determining the formation of their own specific types of cell.* Excessive use of a part or of an organ commonly leads to its hypertrophy, and may thus tend to increase the quantity of hypothetical specific modifier substances arising from such part or organ and reaching the gametes. This would represent a hypothetical physico-chemical mechanism which could in some cases lead to the inheritance of acquired characteristics based on the use or disuse of parts.

Without suggesting a mechanism for their action, J. T. Cunningham³⁸ advanced a Lamarckian view involving hormones as active factors in heredity. He pointed out that special glands are not essential for the production of these internal secretions, for his colleagues at the University of London, W. M. Bayliss and E. H. Starling, had shown (1902) that the wall of the intestine produces a hormone, secretin, which, carried by the blood, causes the pancreas to secrete. Cunningham stated:³⁸ "There is nothing improbable in supposing that a tissue stimulated to excessive growth by external irritation would give off special substances to the blood. We know that living tissues give off waste products, and that these are not merely pure CO_2 and H_2O , but complicated compounds. The theory proposed by me in 1908 was that we have within the gonads numerous gametocytes whose chromosomes contain factors corresponding to the different parts of the soma, and that these factors or determinants might be stimulated by waste products circulating in the blood and derived from the parts of the soma corresponding to them. There is no reason to suppose that an exostosis formed on the frontal bone as a result of repeated mechanical stimulation due to the butting of stags would give off a special hormone which was never formed in the body before, but it would probably in its increased growth give off an increased quantity of intermediate waste products of the same kind as the tissues from which it arose gave off before. These products would act as a hormone on the gametocytes, stimulating the factors which in the next generation would control the development of the frontal bone and adjacent tissues. . . . If the factors in the gametes were thus stimulated they would, when they developed in a new individual, produce a slightly increased development of the part which was hypertrophied in the parent soma. No matter how slight the degree of heredity effect, if the stimulation was repeated in every generation . . . the hereditary effect would constantly increase until it was far greater than the direct effect of the stimulation."

Starling formed the word "hormone" from a Greek root meaning "to stir up" or "excite," and Cunningham uses the term in its original meaning; but in speaking of "endocrines," produced by "glands of internal secretion," the original meaning is limited. Certain substances, ordinarily regarded as waste products of cellular metabolism, are known to affect the activities of organs, and have been called *parahormones*. Thus CO_2 activates the respiratory center of the medulla and is administered with oxygen to avoid respiratory collapse; and the normal heart beat of some lower vertebrates (*e.g.*, sharks) seems to depend upon a certain concentration of urea. The potency of some hormones may be gauged from the finding of J. J. Abel, about twenty years ago, that a purified posterior pituitary hormone is effective in a

* Cells grown in tissue culture often de-differentiate in the course of time.

concentration of 1 part in 18,750,000,000.* Though much is known as to the *effects* produced by hormones, little is known as to the basic *mechanism* whereby these effects are produced. It is suggested that the principle of catalyst modification (including the formation of new catalysts) offers a simple, reasonable, and probable explanation in many cases.

Experimental demonstration of the evolutionary aspect of this principle might appear if tissue cultures of undifferentiated cells could be made to become heritably differentiated by specific substances or extracts.† But past experimental failures do not constitute disproof. The factors involved in most biological processes, though individually simple after discovery, are generally so numerous and obscure that it is very difficult to duplicate all of them in one experiment. Thus many viruses which will not affect adult fowl multiply on the chorio-allantoic membrane of the developing hen's egg. Among those that will *not* grow there are the viruses of poliomyelitis and of foot-and-mouth disease. The culture of orchids from seed became possible after it was found that in nature a symbiotic fungus surrounds the seed with special moisture and other conditions. Lichens commonly found growing on rocks represent a symbiotic system, where a green unicellular alga supplies carbohydrate to a fungus that takes up salts and conserves moisture. Termites would starve to death on their diet of wood, were it not for a parasitic endameba which solubilizes the carbohydrates, as Cleveland found by subjecting termites to a slightly increased oxygen pressure which killed the ameba without injuring the termite itself. Some bionts (*e.g.*, viruses) are termed "obligate" parasites only because we have not yet discovered the conditions essential to their growth and cannot, therefore, yet raise them *in vitro*. Recognition of obscure conditions and of the importance of trace substances or "impurities" is aiding progress in the culture of special forms of life, as well as in an understanding of biological mechanisms.

A Hair perhaps divides the False and True;
Yes; and a single Alif were the clue—
Could you but find it—to the Treasure-house,
And peradventure to THE MASTER too.

- The reader is referred to three papers by the late Prof. Leonard T. Troland (Harvard), from which extensive quotations were given by J. Alexander and C. B. Bridges in the first paper of Vol. II of this series, pp. 18-21. These papers are:
- "The Chemical Origin and Regulation of Life," *Monist*, Jan., 1914.
- "The Enzyme Theory of Life," *Cleveland Medical Journal*, **15**, 377-89 (1916).
- "Biological Enigmas and the Theory of Enzyme Action," *Am. Nat.*, 1917, **15**, 321-50.
- The paper in Vol. II also contains two paragraphs quoted from an unpublished Master's Thesis by J. Alexander, entitled: "The Importance and Trend of Recent Work on the Chemistry of Life and the Products of Life," submitted early in 1899.
- Recently, Prof. Alwin Mittasch (Heidelberg), who did much of the chemical and trace-substance work on the Haber process catalysts (referred to in the quotation from Bernthsen in this paper), published three booklets (Julius Springer, Berlin):
- "Ueber katalytische Verursachen in biologischen Geschehen" (1935).
- "Ueber Katalyse und Katalysatoren in Chemie und Biologie" (1936).
- "Katalyse und Determinismus, Ein Beitrag zur Philosophie der Chemie" (1938).
- The views expressed by Dr. Mittasch seem consonant with those here advanced. In a private communication (March, 1938), following an exchange of publications, he stated:
- "Die 'Modifikation' von Katalysatoren wird ebenso wie die 'Autokatalyse' in der Wissenschaft immer-mehr Bedeutung erlangen. Wenn man aus Erfahrung weiss, was *kleine Änderungen an Katalysatoren* für ein organisches Substrat zu bedeuten haben, so ist klar, dass 'Mutationen' an Katalysatoren für Erkrankungen, Artwandel, u.s.w. von ganz wesentlichem Einfluss sein können. Die Aufgabe für den Wissenschaftler ist dabei immer zweifach:
- (1) Wie *entsteht* die Änderung von Katalysatoren?
 - (2) Welche *Wirkungen* hat das für das Substrat?
- Die Physiologen werden darauf sehr zu achten haben."

Photosynthesis

PAUL ROTHMUND

The C. F. Kettering Foundation for the Study of Chlorophyll and Photosynthesis,
Antioch College, Yellow Springs, Ohio

The term *photosynthesis* refers, in general, to the synthesis of chemical compounds effected with the aid of radiant energy, especially in the visible region of the spectrum; more specifically the name is applied to the formation of complex organic substances in the tissues of plants exposed to light. Usually the statement is made that the green plant is the converter of the supply of solar energy into the chemical energy of the structural material of the plants on earth. This is true for a relatively large number of compounds produced; but some lower plants, which do not contain chlorophyll, also show photosynthetic activity. Other lower plants effect strictly chemical syntheses, without the necessity of being exposed to light.

In the following discussion an attempt has been made to summarize and coordinate recent publications on photosynthesis, omitting, however, numerous tentative explanations as well as papers of purely speculative character; it is hoped that within the limitations of space the essence of our present knowledge is adequately presented. Chemical formulas for the chlorophylls *a* and *b*, and for other pigments possibly involved in the process, and a discussion of the reactions of these colored compounds are also not included; instead, the reader is referred to recent reviews on the chemistry of chlorophyll.¹⁻³ The term *chlorophyll* will be used for the green coloring matter, extractable from green parts of plants as a mixture of the two pigments chlorophyll *a* and *b* (usually in the proportion *a* : *b* = 3 : 1).

The many interpretations proposed to elucidate the mechanism of the process may be classified into four groups:

- (1) Chemosynthesis (chlorophyll and light not necessary)
- (2) Photosynthesis in the absence of chlorophyll (other pigments in the cells may be necessary)
- (3) Photosynthesis in the presence of chlorophyll, the latter acting as a sensitizer, as a light filter, or as an absorber and transmitter of radiant energy.
- (4) Photosynthesis with chlorophyll participating in one or more chemical reactions. In this case chlorophyll may react either as such, or in a complex compound consisting of chlorophyll as the prosthetic group on a large molecule as carrier; the carrier is supposedly not directly engaged in the reaction.

Reaction mechanisms for each of these four types of fundamental concepts are given in the more recent books on photosynthesis⁴⁻⁹ and in the "Annual Review of Biochemistry." It should be remembered that many conclusions drawn from biological experiments hold for only one family of plants, or even for only one species; at present investigators more frequently select pure cultures of green algae or of bacteria for their work, while leaves or other chlorophyll-bearing parts of higher plants are used to a much lesser extent. Thus far no generalization on the photosynthetic behavior of these different plants can be made, although many interesting and important individual facts have been recognized. Thus it has been found that a number of algae may be trained by varying the conditions of growth; the qualitative and quantitative results of photosynthetic performance depend on such previous training.

The question as to the degree of efficiency attained by the plant in the use of energy from the sun for the reduction of carbon dioxide seemed to have been definitely answered by Warburg and Negelein.¹⁰⁻¹² These authors used monochromatic radiation on *Chlorella* (sp. ?; see footnote to Table 2) and found the following quantum efficiency:

Table 1

| Wave Length (mμ) | Spectrum Region | Corresp. Energy (Cal./Mole) | Quanta required per mole CO ₂ | Quantum Yield (Mole CO ₂ per quantum) |
|------------------|-----------------|-----------------------------|--|--|
| 660 | Red | 43,000 | 4.4 | 0.23 |
| 578 | Yellow | 49,200 | 4.3 | 0.23 |
| 436 | Blue | 65,100 | 5.1 | 0.20 |

The value for the quantum yield (or quantum efficiency) for the red region

$$\frac{\text{decomposed CO}_2}{\text{quanta per mole}} = \frac{1 \text{ mole CO}_2}{4} = 0.25$$

seemed to explain the basic reaction

so well that a large number of authors accepted Warburg's value of 0.25 mole carbon dioxide per quantum as "classical" * and based their own calculations on it. Reinvestigations of Warburg's work in different laboratories established the fact that the values for the quantum yield deviate considerably from the value of 4; a tabulation of some of the results of different authors is given on p. 602.

The table shows that at present no reliable numerical statement for the quantum yield in photosynthesis can be made. Even an evaluation of the individual data for

* This epithet has been attached by some investigators in the field of chlorophyll and photosynthesis to the concept of 4 quanta, and to a number of other statements in the older literature. Since it has meaning only as of a specific period of time, and is of necessity arbitrary, its use has always been confusing rather than defining, and should, therefore, be discontinued.

comparison is not permissible, since the limits of error for the measurements by the different authors are not in every case known, and since technique and method of computation vary also to some extent. In spite of this wide discrepancy of data, some investigators believe it justifiable temporarily to assume 12 quanta as the most probable value.

Table 2. Determination of the Quantum Yield in Photosynthesis

| Author | Year | Reference | Organism | Quantum Yield |
|------------------------------------|-------------|-----------|---|---------------|
| Warburg, Negelein | 1922-3 | 10-12 | <i>Chlorella vulgaris</i> * | 4-5 |
| French | 1936-7 | 13 | <i>Streptococcus varians</i> | 4 |
| " | | 14 | " | 4-16 |
| " | 1937-8 | 15 | <i>Spirillum rubrum</i> | 17 |

| Eymers, Wassink | 1938 | 18 | <i>Chromatium</i> | 12-18 |
| Rieke | 1939 | 19 | <i>Chlorella pyrenoidosa</i> | 4.2 |
| Petering, Duggar, Daniels | 1939 | 20 | " | 10-25 |
| Magee, DeWitt, Smith, Daniels | 1939 | 21 | " | 12.5 |
| Eichhoff | 1939 | 22 | " | 4 |
| Eichhoff, Noddack | 1939 | 23 | " | 4 |
| Emerson, Lewis | 1940 | 24 | " | 10-11 |
| Rieke | unpublished | 25 | <i>Chlorella Scenedesmus</i> | 11-14 |

* Although Warburg states specifically that his values were obtained with *Chlorella vulgaris*, Emerson and Green²⁶ conclude, on the basis of their taxonomical and physiological studies of *Chlorella vulgaris* and *Chlorella pyrenoidosa*, that Warburg's material must have been *Chlorella pyrenoidosa*.

Photosynthesis in the plant involves at least two steps:

- (a) the photochemical reaction, for which the chemical effect produced by the unit of absorbed radiant energy is characteristic,
- (b) a chemical reaction, often also called "dark reaction," "thermal reaction," or "Blackman reaction,"²⁷ which precedes or follows the photochemical reaction, and is entirely independent of irradiation.

The duration of the Blackman reaction is obviously a limiting factor for the photochemical part of photosynthesis; on the green alga *Chlorella pyrenoidosa* Emerson and Arnold^{28, 29} determined the time required for this reaction as 0.02 second at 25°, when light flashes of 10⁻⁵ second duration were alternating with dark periods. The same authors calculated that for each molecule of carbon dioxide reduced per flash of light approximately 2,500 molecules of chlorophyll are present. In following up this work Arnold and Kohn³⁰ found that in six species of plants, representing four phyla, the minimum number of chlorophyll molecules available for the reduction of one molecule of carbon dioxide is about 2,000. This result suggested the existence of a "chlorophyll unit," and gave rise to the hypothesis of a photosynthetic unit. This hypothesis aims to show that through a cooperative effort of a large number of chlorophyll molecules enough light is absorbed at any given time by the unit to reduce one molecule of carbon dioxide.

The assumptions concerning the nature of this unit vary considerably. Gaffron and Wohl³¹ calculated (on the basis of Warburg's photosynthetic yield of 4 quanta) the number of chlorophyll molecules actually involved in the process of carbon dioxide reduction and found a value of 1,000. They postulated, however, that the plant may be able to adjust itself to the conditions of illumination by varying the number of chlorophyll molecules in the unit. Shortly afterwards Wohl³² changed this picture by introducing the concept of an energy carrier. The individual chlorophyll molecules transfer radiant energy to other kinds of molecules ("energy carriers") and the latter carry it to reduction centers. The number of such centers is supposed to be several thousand times smaller than that of chlorophyll molecules.

Van Niel³³ considers photosynthesis by green plants "a complex of photochemical and dark reactions in which the former consists of a photodecomposition of water," (as hydrogen donor) "with the aid of chlorophyll and enzymes of unknown nature." A combination of Wohl's and Van Niel's ideas can be found in a recent paper by Ornstein and co-workers.³⁴

The assumptions of a photosynthetic unit rendered it necessary to determine whether the known facts on photosynthesis could be satisfactorily explained without resorting to the concept of such a unit. Here the work of Franck and co-workers must be mentioned. Franck and Gaffron³⁵ replaced their former theories on photosynthesis by a new one, which assumes a number of coupled reactions, involving the change of chlorophyll to monodehydrochlorophyll, and the formation of stable and unstable reaction intermediates by means of hypothetical catalysts "A," "B," and "C." Some of the intermediate products, supposedly of peroxide nature, furnish the oxygen evolved during the reaction, and at the same time restore the hydrogen necessary for the regeneration of chlorophyll. This theory incorporates portions of the concepts by Fischer, Kautsky, Richter, Stoll and Willstätter, and takes into consideration such well-established experiments as the change of fluorescence and the behavior of "poisons" in the process of photosynthesis. But the authors are well aware of the shortcomings of their attempted explanations, especially since the preparation and isolation of the assumed reaction intermediates is completely lacking.

It is important to keep in mind that thus far all experimental attempts to perform photosynthesis *in vitro* have been failures. This fact has often been used as an indication that the special structure of the chloroplast may be the decisive factor in the assimilation of carbon in plants. The comparison of chlorophyll with the hemoglobin in mammalian blood suggests itself: chlorophyll may be present in the plant as a protein-chlorophyll complex compound similar to hemoglobin, which contains 96 per cent of the histone globin, and 4 per cent of the prosthetic pigment group. The application of this concept to the photosynthetic unit renders photosynthesis a problem in colloidal chemistry. The photosynthetic unit would then be a macromolecule made up of a large number of protein molecules to which chlorophyll molecules have been added. Several experiments seem to indicate the existence of such a protein-chlorophyll complex.

As early as 1912 Herlitzka³⁶ prepared water suspensions of spinach cell material without change of the spectral properties of the green pigment; similar suspensions were reported by Wurmser,³⁷ who obtained them from ground cultures of purple bacteria. These suspensions probably contained a portion of the protein and of the pigment in form of particles of colloidal size. The presence of a protein-chlorophyll complex in the green plant was suggested by Lubimenko,³⁸ and later by Stoll.³⁹

For compounds formed through action of residual affinities from high molecular substances or complex compounds Willstätter⁴⁰ suggested the term *symplex*. This is supposed to include systems consisting of a high molecular carrier and a prosthetic group, as well as systems composed of several components of high molecular weight; it is applicable also to organic substances to which an inorganic compound is linked. Stoll assumes that the chlorophyll in the chloroplasts is linked to a colloidal carrier

to form a highly active symplex. In analogy to hemoglobin the name "chloroplastin" was suggested for this symplex. Chloroplastin has not been isolated from the plant so far in spite of numerous attempts in this direction. Stoll believes that chlorophyll owes its activity in photosynthesis to the linkage to a certain colloid, and that the chloroplastin symplex thus formed becomes the "assimilatory enzyme" of the plant. The long branched hydrocarbon chain of phytol accounts for the solubility in lipoids, and may anchor the chlorophyll to fats or related substances.

Since the chloroplastin hypothesis touches on the problem of the condition of chlorophyll in the leaf, a few studies on this subject may be mentioned. Baas-Becking⁴¹ says "The theory is proposed that chlorophyll is present in small particles in the periphery of the plastid, adsorbed, on its lipophilic side, on lecithin, and on its hydrophilic side, on protein." In searching for a technique to prepare photochemically active water solutions of the cell contents, French⁴² found that the cells of purple bacteria will break up in a few minutes, when they are exposed to sound waves of a frequency of 15,000 to 21,000 cycles/sec. Using *Streptococcus varians* and *Spirillum rubrum* in the vibrator, the decrease of the photosynthetic activity ran parallel with the process of pigment liberation from the cells, and the protein-containing pigment was not appreciably changed by the extraction method with sound waves. French suggested a distinguishing nomenclature: the name *chloroplastin* should be reserved for compounds with ordinary chlorophyll from higher plants and yellow green algae; *photosynthin* is suggested as a general term for compounds of photosynthetic activity, such as the combination bacterio-chlorophyll and protein.

The protein-chlorophyll combination undergoes very interesting changes when it is exposed to the action of proteolytic enzymes. Such experiments were performed by Inman⁴³ with trypsin in buffered solutions in the presence and absence of carbon dioxide, and the spectroscopic changes of the pigment component were measured. It was concluded that chlorophyll may be linked to the substrate for the enzyme by a magnesium-protein linkage. The absorption spectra of individual chloroplasts in living cells have been determined for *Protococcus*, *Spirogyra*, and *Euglena* by Albers and Knorr.⁴⁴ The results indicated either that there are other pigments present, which give absorption similar to that of chlorophyll *a*, or that chlorophyll *a* enters into the photochemical reaction in photosynthesis in several steps, forming reaction products with absorption bands at slightly different wave lengths. The first assumption may have significance in the light of the investigations of Strain and Manning;⁴⁵ they report that diatoms and brown algae normally contain chlorophyll *a*, and another chlorophyll-like pigment, which is different from chlorophyll *b*. For this pigment the name *chlorophyll c* or the old names *chlorofucine* (Sorby, 1873), or *chlorophyll γ* (Tswett, 1906) are suggested; the absorption spectrum and data for the isolation of the pigment are given. Since in certain regions of the spectrum chlorofucine absorbs considerably more light than chlorophyll *a*, it is considered possible that chlorofucine may play an important role in the process of photosynthesis.

The evolution of oxygen has been used in many investigations as the measure of photosynthetic activity. Recently this method of determination was applied to isolated chloroplasts by Hill and Scarisbrick.⁴⁶ At pH 8 the irradiation of isolated chloroplasts of *Stellaria media* in potassium ferric oxalate caused reduction of the trivalent iron under evolution of oxygen in the absence of carbon dioxide. This interesting result can, of course, not be interpreted as a successful performance of photosynthesis *in vitro*.

Undamaged chloroplast material from spinach leaves was isolated and analyzed by Menke;⁴⁷ the results are given in Table 3, together with the data for chloroplast substance.

From the difference in composition Menke calculated a content of cytoplasm material in the chloroplasts of approximately 15 per cent, or for the dry leaf 17.9 per cent

chloroplast substance and 16.7 per cent cytoplasm substance. The protein fraction of chloroplasts consists of about 80 per cent protein and 14.6 per cent nitrogen. After removal of the lipoids from the chloroplasts, a protein can be extracted, which contains phosphorus in a pentose nucleic acid. These experiments show the localization of phosphorus in the chloroplasts, not in the cytoplasm. A manometric study of the

Table 3

| | Chloroplasts entire (%) | Chloroplast substance (%) |
|-----------------------------|-------------------------------|---------------------------------|
| Protein ($N \times 6.25$) | 47.7 | 56.4 |
| Ether-soluble ("Lipoids") | 37.4 | 31.9 |
| Ash | 7.8 | 4.7 |
| Undefined | 7.1 | 7.0 |

gas metabolism of isolated chloroplasts demonstrated their inability to carry on photosynthesis; they were, however, able to perform a photooxidation, since they used up more oxygen during irradiation than they did in the dark.⁴⁸

Smith^{49, 50} prepared aqueous solutions or suspensions of the green pigments by means of digitonin, and—following Mestre's suggestion⁵¹ of a name for this type of chromoprotein—called the resulting material *phyllochlorin*.* The spectra of these solutions resemble spectroscopically those of chlorophyll in the leaves, and differ from the spectra of extracted chlorophyll.

Table 4. Absorption Spectra in Ethyl Ether

| | | | |
|-----------------------|-----|-----|-------------|
| "Phyllochlorin" | 675 | 470 | 437 m μ |
| Extracted Chlorophyll | 660 | 465 | 420 m μ |

A preliminary investigation of the molecular weight of "phyllochlorin" by means of the ultracentrifuge gave a value higher than 70,000 for this chromoprotein. Further purification showed a constant relation of about 16 parts of chlorophyll per 100 parts of protein, indicating a little over 3 molecules of chlorophyll per Svedberg protein unit of molecular weight 17,000; this fraction over 3 was interpreted as being possibly an extra molecule of chlorophyll *b*. "Phyllochlorin" is rendered water-soluble by the action of various detergents, such as bile salts, sodium desoxycholate, or sodium dodecylsulfate. The latter compound clarifies the solution completely, at the same time converting the chlorophyll quantitatively into pheophytin. The rate of this conversion depends on the hydrogen-ion concentration; it takes place even at pH 8–9, and is, at constant pH, proportional to the sodium dodecylsulfate concentration. Pheophytin formation does not occur in 4 per cent digitonin, or in 10 per cent bile salt solution at pH 4.5. At this pH a suspension of pure chlorophyll would be converted into a suspension of the magnesium-free pheophytin. In contrast to Inman (see⁴³), Smith considers it improbable that magnesium plays a part in linking chlorophyll to the protein, but he believes that it may be concerned with the binding of larger units. "Phyllochlorin" does not carry on photosynthesis *in vitro*.

Special attention was paid to the size of the parenchyma cells used in a set of analyses of chloroplast material from tomato and tobacco leaves, performed by Granick.⁵² At $\frac{1}{3}$ maximum size the cells contain only about $\frac{1}{10}$ of the total nitrogen and protein, which they contain at $\frac{2}{3}$ maximum size; the difference between a cell of the latter size and one of maximum size is, however, very small: the cell of maximum size has only 0.25 per cent more nitrogen than the cell of $\frac{2}{3}$ maximum size. Granick concludes from his analyses that for a molecular weight of 100,000 of the chloroplast protein there are approximately 30 chlorophyll molecules per protein molecule in the chloroplast. Per Svedberg protein unit of molecular weight 17,000,

* This term must not be confused with the chemical term phyllochlorin for the chlorin (= 7.8 – dihydro-derivative) of phylloporphyrin (see¹⁻³).

this would mean approximately 5 chlorophyll molecules as compared with the foregoing value of 3 to 4.

The availability of radioactive elements in suitable compounds renders it possible to use such "tagged" elements in tracing reaction products. Thus the rate of photosynthesis by *Chlorella pyrenoidosa* with radioactive carbon dioxide ($^{14}\text{CO}_2$) was determined by Ruben and co-workers.⁵³ Using the Warburg manometric method and simultaneously the radioactive technique, they find that carbon dioxide reduction is markedly affected by such poisons as hydrogen cyanide or phenyl urethane. At hydrogen cyanide concentrations of 10^{-2} to 10^{-3} molar, the respiration remains unchanged, but photosynthesis is strongly inhibited. *Chlorella* cells reduce $^{14}\text{CO}_2$ reversibly in the dark (thermal reaction), and the radioactive intermediate products contain most of the radio carbon in form of carboxyl. The reaction may be written:

The authors suggest that it is the presence of the radioactivity in the carboxyl group which renders the formation of this group energetically and structurally possible. Later Ruben⁵⁴ investigated this reaction more thoroughly; from a comparison of the equilibrium constant for carbon dioxide fixation in *Chlorella* with the known equilibrium constants for simple carboxylations he concludes that the primary reaction in photosynthesis does not consist solely of a carboxylation as given above, but must involve a more complicated sequence of reactions. He bases his explanation on the studies of phosphorylation reactions,⁵⁵ and assumes a reaction scheme in which an energy-rich phosphate donor phosphorylates the carbon dioxide acceptor $\text{R} - \text{H}$ (possibly an aldehyde), and the latter then reacts with carbon dioxide with formation of a carboxylic acid; if $\text{R} - \text{H}$ is an aldehyde—and the author claims to have some indirect evidence for this assumption—an α -ketonic acid would be the reaction intermediate. In summary the scheme is represented by the following equations:

or, for the assumption of an aldehyde

The photochemical process is formulated by Ruben only in a general form:

where AH, or AH_2 , and BOH, or BO merely symbolize oxidizing and reducing agents; it is claimed that "10 to 12 quanta are more than sufficient to fill the requirements of the above 'theory.'"

With the assumption of enzymes as reaction partners in photosynthesis it has always been important to determine the range of hydrogen-ion concentration within which the process is performed in nature. A large number of investigations deal with this subject; it must suffice here to mention that determinations in terms of pH have been made of the external hydrogen-ion concentration, *i.e.*, of the reaction medium in which the cells were grown, and also for the surface and for internal

conditions of the cells. The latter measurements are, of course, more complicated, and offer a greater possibility for errors.

At saturation concentrations of carbon dioxide the rate of photosynthesis by *Chlorella* does not change, when the external pH value varies between 4.6 and 8.9.⁵⁶ The changes of pH of cells and cell suspensions, and of suspensions of cell contents, and also of the oxidation-reduction potentials during photosynthesis have been studied by widely differing techniques, and under many variations of conditions, e.g., under constant illumination, under alternating light flashes and dark periods, both of varied duration, in atmospheres of air, oxygen, or carbon dioxide, and of mixtures of these gases. For the measurements of the rates of photosynthesis and of respiration the dropping mercury electrode,⁵⁷ the glass electrode,⁵⁸ a platinum electrode,⁵⁹ and a bright platinum electrode polarized cathodically⁶⁰ have been used. A very interesting change was noticed by Blinks (see⁵⁸) on *Stephanoptera* suspensions: intermittent light flashes of 0.02 second duration produced an acid gush, before an alkaline drift occurred. Upon darkening, a brief alkaline reaction was followed by the slower acid drift of respiration. Blinks discusses several possibilities as explanations for this acid effect:

- (a) Release of carbon dioxide by some photolabile holding mechanism;
- (b) Increased respiration in light in excess of photosynthesis;
- (c) Production of an acid stronger than carbon dioxide as the first product of photosynthesis;
- (d) Photodecomposition of compounds;
- (e) Increased consumption of a base during the first moment of illumination.

For the first assumption, the existence of a photolabile holding mechanism, Shafer⁶¹ furnishes a number of additional experimental data. In his opinion chlorophyll is not a factor concerned in the light-activated adsorption of carbon dioxide by leaves; it is the special holding mechanism which retains part of the carbon dioxide, either by adsorption, or in loose chemical linkage.

An important factor in discussions on photosynthesis is the assimilation of carbon dioxide by chlorophyll-free plants. There the absorption of radiant energy may be performed by other pigments; thus bacteriochlorophyll in the purple bacteria may be a parallel to chlorophyll in green plants. The two pigments are closely related chemically. Fischer⁶² demonstrated the presence of magnesium in bacteriochlorophyll, and established its structural formula. For the assimilatory performance of bacteria reference must be made to the article by Van Niel already mentioned.³³ Van Niel concludes from the evidence now at hand that there is no reason to suppose a fundamental difference of photosynthesis in purple bacteria and in green plants. He assumes only the necessity of the presence of "appropriate hydrogen donors" (symbolized by H_2A in the following scheme) in the purple bacteria, and formulates his working hypothesis, with carbon dioxide as the substance to be reduced, for

In the light of the work of Ruben and co-workers, the reduction process may, however, involve another substance, and in that case formaldehyde as the reaction intermediate is replaced by an intermediate with more than one carbon atom in the molecule.

The question of chlorophyll development in green plants under the influence of radiation has remained unanswered thus far in spite of many studies in this field.⁶³ In most plants chlorophyll development requires a photochemical change of a colorless precursor of chlorophyll; for this precursor a number of names are used in the

literature: colorless chlorophyll, chlorophor, leucophyll, etiolin, protophyllin, and protochlorophyll.⁶⁴ Protochlorophyll has been identified by Fischer⁶⁵ as the magnesium complex salt of the vinyl-pheoporphyrin α_5 phytyl ester; but the problem whether protochlorophyll is actually the precursor, or whether it is a decomposition product of chlorophyll, remains still unsolved (see Ref. 1, vol. II/2, pp. 321-4).

It has been pointed out by Kostytschew⁶⁶ that photosynthesis in the green plant during the day is irregular, and that sometimes an intensive carbon dioxide elimination replaces the normal uptake of this gas. He suggests measurements of the total daily production of organic materials by the plant under natural conditions in order to remove this possible source of error.

The determination of the amount of radiation actually taken up by green leaves is at present also a subject of controversy. Lasareff⁶⁷ states that leaves absorb twenty times as much light as chlorophyll solutions, and that the energy falling on a leaf is absorbed with a loss of only 1-2 per cent; hence leaves may be regarded as absolutely black bodies. Other authors give data for much higher losses, and point out that structural and physiological conditions (*e.g.*, hairiness and age), or pathological conditions (like presence of mildew, or excessive radiation) may change the rate of light absorption. In his discussion of this subject Mestre⁶⁸ analyzes the photometric problem involved, and concludes that the present unsatisfactory state of accumulating "first approximation data" by a large variety of techniques on an increasing number of species must be changed to a thoroughgoing agreement on instrumental methods.

A much discussed problem is the fluorescence of photosynthesizing leaves. According to Kautsky,⁶⁹ the total amount of energy necessary in the process is absorbed by chlorophyll and transferred to the assimilatory system. This transfer is accompanied by a quenching of the fluorescence; and since oxygen is known to extinguish chlorophyll fluorescence, it is assumed that oxygen is acting as a collecting and transferring agent of the energy in photosynthesis. There is, on the other hand, much evidence that the presence of oxygen is not an absolute requirement in the process. The fluorescence of the leaves is very low, indeed, as compared with that of chlorophyll in solution. For such solutions under different atmospheres (air, oxygen, carbon dioxide, and nitrogen) detailed studies are available.^{70, 71} But the exact correlation of absorption of light by the green leaf and re-emission in form of fluorescence is still lacking.

Only a fraction of the total incident radiation from the sun is used by the plant in photosynthesis; the balance is expended in other ways such as re-radiation, transpiration, thermal transmission, and respiration. The basic equation for the reduction of carbon dioxide (p. 606), in the form usually given, namely with a hexose (glucose) and oxygen as end products, is:

The heat of combustion of glucose (mol. weight 180.16) is 673.0 kg-calories₁₅ per gram molecular weight (2,816.5 kilo Joules). This value, the amount of energy fixed in the process and reclaimable by combustion,⁷² is obviously the minimum requirement for performing the reaction. The determination of the amount of energy necessary above this minimum to photosynthesize glucose has not yet been performed. Actually the reaction is highly improbable in the simple form given above, since carbon dioxide most certainly does not react as gas, but dissolves in water with formation of H^+ and HCO_3^- ions in equilibrium with undissociated H_2CO_3 . Baly⁸ pointed out that for the reaction

performed in one step, the wave length of light necessary would be 253.5 m μ , while the light of the sun reaching the earth does not contain wave lengths below approxi-

mately 290.0 m μ . This consideration illustrates one of the greatest difficulties in the present status of our experience concerning photosynthesis, namely the lack of information as to the number of chemical and photochemical reactions, and the quantity of solar energy used to bring about these reactions.

The assumption of a photosynthetically active symplex of a colloidal nature seems to explain the energetic difficulties very well, but the isolation of chemically defined intermediates is still an unfinished task. The validity of any of the numerous hypotheses and theories on photosynthesis can be tested only by the ultimate experimental performance of obtaining such intermediate compounds, and by accomplishing the process itself *in vitro*.

Plant Cell Membranes

WANDA K. FARR*

The nature of the processes by which plants produce complex, organic substances from simple, inorganic materials was a clearly defined biological and chemical problem at the beginning of the nineteenth century. Shortly before 1840 two important advances toward its solution were made. The classification of organic substances into carbohydrates, proteins, and fats by Prout²⁰⁴ occurred almost simultaneously with the recognition by Schleiden²²⁶ and Schwann²³² that "All organized structures are composed of essentially similar units, namely *cells*." The approach to a clearer understanding of the synthetic power of living plants was thus changed from a state of more or less general speculation to one of direct observation and experimentation. The methods of study used by these nineteenth-century investigators were largely microscopic and chemical, and their inheritance, in terms of apparatus and procedures, from scientists of the preceding eras, was of great value.

Development of Chemical Techniques

The foundation of organic chemistry had been built by Lavoisier in the eighteenth century (1743-1794), and among his immediate successors in this field of research were Berzelius (1779-1848), Gay-Lussac (1778-1850), Liebig (1803-1873), and Wöhler (1800-1882). During the early part of the nineteenth century their methods of identification and analysis were used to promote the understanding of the chemical and physical properties of many different organic substances.

Kirchhof¹⁴³ in 1816 described the reactions which alter starch and transform it partially into gummy material and sugar. Braconot³⁰ in 1825 removed the sugars from finely divided vegetable material and heated the residue with dilute HCl followed by dilute NaOH. A thick, mucilaginous solution was filtered from the residue. When acidified, it was transformed into a voluminous jelly which he called *pectic acid*. In a later publication Braconot³¹ reported the extraction of at least a portion of the pectic compounds from plant tissues by treatment with water alone. This opaque, mucilaginous solution was precipitated by alcohol in the form of a firm jelly. He suggested that this water-soluble, gelatinous compound should be named *pectin*. Fremy⁶⁹ was the first to recognize the presence of an insoluble substance of pectic nature in plant tissues; to it he gave the name *pectose*. He believed this to be an insoluble salt of calcium or potassium which, when acted upon by acids, gives rise to free pectin and bases. He was not able to remove the pectose from plant tissues without bringing about its decomposition.

* A contribution from the former Cellulose Department of the Chemical Foundation, Boyce Thompson Institute for Plant Research, Inc., Yonkers, New York.

Prout²⁰⁴ obtained a firmer grasp upon the more general aspects of organic analyses through his recognition, in 1827, that the principal alimentary substances employed by man can be classified as *saccharine*, *oily*, and *albuminous*. In his discussion of carbohydrates (p. 375) he states, "Starch differs from sugar by containing minute portions of other materials which, we may presume, prevent its constituent particles from arranging themselves in crystalline form and thus cause it to assume totally different properties."

Prout was at first at a loss to form any notion of the *modus operandi* of these minute admixtures of foreign bodies. A paper published by Herschel¹¹² in 1824, dealing with certain motions produced in fluid conductors when transmitting an electric current, threw new light upon the subject and led Prout to comment, "That such minute proportions of extraneous matter should be found capable of communicating sensible mechanical motions and properties of a definite character to the body with which they are mixed, is perhaps one of the most extraordinary facts that has yet appeared in chemistry. When we see energies so intense exerted by the ordinary forms of matter, we may reasonably ask what evidence we have for the imponderability of any of the powerful agents to which so large a part of the activity of material bodies seems to belong." He expressed the belief that small quantities of any substance may be capable of functioning in such a capacity, and suggested that water is first in importance, in this respect, in organized substances. Prout's treatise contains methods of separation and combustion analyses of a large number of organic substances such as *lignin*, *starch*, *mannan*, *gum arabic*, *oxalic acid*, *citric acid*, and *tartaric acid*; it serves as a fitting example of achievements in the field of organic chemistry up to and including the first quarter of the nineteenth century.

The classification of chemical substances into crystalloids and colloids by Graham⁹⁴ was of fundamental importance in the interpretation of the composition and behavior of organic materials. Early applications of his findings are to be found in the work of Rainey,²⁰⁵ who pointed out that crystalline substances, normally angular in form, are made to assume globular form by deposition in viscous or gummy substances. He considered the possibility that the viscosity of the gum annuls the polarity of the crystal, and allows the molecules of the crystal to obey simple laws of common and mutual attraction. He showed that, when calcium carbonate crystals are formed in a solution of gum arabic, a portion of the gum is enclosed or intermixed. He termed this phenomenon *molecular coalescence* and produced its counterpart, *molecular disintegration*, by immersing the crystals so formed in solutions of higher viscosity than those in which they were produced. Harting¹⁰⁸ found, likewise, that crystals of calcium carbonate, formed in a solution of albumen, were in the form of "calcosphaerites" and that the albumen contained in the calcosphaerites had undergone a chemical change which caused it to resemble *chitin*. Ord¹⁹¹ extended the studies of Rainey to other crystalline substances, including uric acid and such colloids as albumen, gelatin, amyloid, and pectin; he found that when a crystalloid is deposited from solution in the presence of a colloid the crystals are broken down into spheres, or spheroids, or molecules, by the action of the colloids. The colloidal properties of both cell membrane materials and the protoplasts from which they are formed made these considerations of great importance in both the chemical and microscopic analyses of plant tissues. It is somewhat surprising to find that they received little immediate attention in this field of research and that this situation continues, in a measure, up to the present time.

Development of Microscopic Techniques

During the later Middle Ages magnifying glasses were made consisting of a single glass lens in the form of a segment of a sphere, mounted in a wooden tube, with provision for focusing. Small lenses of short focal distances, fashioned in the hands of skilled artisans, and mounted in silver or brass, magnified properly mounted

I could exceeding plainly perceive it to be all perforated and porous, much like a Honey-comb, but that the pores of it were not regular; yet it was not unlike a Honey-comb in these particulars.

First, in that it had a very little solid substance, in comparison of the empty cavity that was contain'd between, as does more manifestly appear by the Figure A and B of the XI. *scheme*, for the *Interstitia*, or walls (as I may so call them) or partitions of those pores were neer as thin in proportion to their pores, as those thin films of Wax in a Honey-comb (which enclose and constitute the *sexangular cells*) are to theirs.

Next, in that these pores, or cells, were not very deep, but consisted of a great many little Boxes, separated out of one continued long pore, by certain *Diaphragms*, as is visible by the Figure B, which represents a sight of those pores split the long-ways.

I no sooner discern'd these (which were indeed the first *microscopical* pores I ever saw, and perhaps, that were ever seen, for I had not met with any Writer or Person, that had made any mention of them before this) but me thought I had with the discovery of them, presently hinted to me the true and intelligible reason of all the *Phænomena* of Cork; As,

First, if I enquir'd why it was so exceeding light a body? my *Microscope* could presently inform me that here was the same reason evident that there is found for the lightness of froth, an empty Honey-comb, Wool, a Sponge, a Pumice-stone, or the like; namely, a very small quantity of a solid body, extended into exceeding large dimensions.

FIGURE 1. Drawing of cellular structure of cork and accompanying description from Hooke's "Micrographia," 1665.

objects from 50 to 300 times their original diameters. Such instruments were called *microscopes*.

The *compound microscope*, invented by Hans and Zacharias Janssen²⁸ in 1590, consisted of two lenses, one placed near the eye of the observer, the other near the object, a principle of construction fundamental in microscopes used at the present time. Images formed with the compound microscopes left much to be desired, skillful observers seeing as much, if not more, with the simple microscopes. This was

Observ. 4.. Of Tabby.

A short description of it. A conjecture about the reason why Silk is so susceptible of vivid colours: and why Flax and Hair is not. A conjecture, that it may perhaps be possible to spin a kind of artificial Silk out of some glutinous substance that may equalize natural Silk.

trant, juyces or liquors. And thereby those tinctures, though they tinge perhaps but a small part of the substance, yet being so highly impregnated with the colour, as to be almost black with it, may leave an impression strong enough to exhibite the desir'd colour. A pretty kinde of artificial Stuff I have seen, looking almost like transparent Parchment, Horn, or Iling-glass, and perhaps some such thing it may be made of, which being transparent, and of a glutinous nature, and easily mollified by keeping in water, as I found upon trial, had imbib'd, and did remain ting'd with a great variety of very vivid colours, and to the naked eye, it look'd very like the substance of the Silk. And I have often thought, that probably there might be a way found out, to make an artificial glutinous composition, much resembling, if not full as good, nay better, then that Excrement, or whatever other substance it be out of which, the Silk-worm wire-draws his clew. If such a composition were found, it were certainly an easie matter to find very quick ways of drawing it out into small wires for use. I need not mention the use of such an Invention, nor the benefit that is likely to accrue to the finder, they being sufficiently obvious. This hint therefore, may, I hope, give some Ingenious inquisitive Person an occasion of making some trials, which if successful, I have my aim, and I suppose he will have no occasion to be displeas'd.

FIGURE 2. Photographic reproduction of Hooke's statement.

due to the presence of chromatic and spherical aberrations in the objectives of the compound microscopes. A simple lens of extremely short focal distance is not defective in these respects. It was not until the first quarter of the nineteenth century that the necessary corrections to the objectives were made, and the supremacy of the compound microscope over the simple microscope thus established.

Before the close of the seventeenth century, the first important observations of the microscopic structure of plants, animals, and inorganic substances, at magni-

fications as high as 500 diameters, had been made by the Dutch microscopist, Leeuwenhoek,¹⁵⁴ the English mathematician and microscopist, Hooke,¹³³ (Fig. 1), the English physician and botanist, Grew,⁹⁵ and the Italian physician and physiologist, Malpighii.¹⁶¹ In the works of these early writers' occasional comments as to the relation of microscopic structure to function and gross physical behavior also occur. One of these instances, of important prophetic significance, is to be found in Hooke's *Micrographia*.^{188, p. 7}

Having recognized, in the course of his observations, the plastic properties of plant tissues, Hooke thus covered, in one sweeping statement, the fundamental principles of artificial-silk manufacture, an industry not developed until more than two centuries later.³⁹

Rapid improvements in the design and construction of the compound microscope transformed it from a two-lens into a many-lens instrument in which spherical aberration was largely overcome by means of suitable forms and combinations of lenses. The important researches of Dolland (1758), Euler (1771), Fuss (1774), and Fraunhofer (1815) laid the foundation for the correction of chromatic aberration. Transmitted light, obtained by placing the illuminating reflector under the object, was introduced in the year 1735 by Culpepper and Scarlet.¹⁰⁷ Instruments, in which microscopic observations were no longer hindered by either marked spherical or marked chromatic aberrations, were available, therefore, early in the nineteenth century. The impetus to the microscopic study of plant tissues during this period was thus linked inextricably with improvements in the microscopes themselves.

Under these favorable conditions many of the chemical techniques were adapted to microscopic observation and the science of *microchemistry* had its beginning. Carbohydrates, fats, proteins, and other organic materials were identified not only separately in the test tube, but also microchemically in plant tissues, thus furnishing added information concerning their relative functions in building up the highly complex organ, endowed with synthetic powers of unknown nature—the plant cell. The microscopic and chemical data, which were rapidly accumulated by botanists and chemists during the first half of the nineteenth century, constitute the foundations upon which we have continued to build to the present time. Many of their methods of identification are in use today with little modification.

Plant-cell Membranes

In the greater number of living plant cells there are visible two distinctly different parts: the delicate, more or less viscous protoplast, and the comparatively rigid cell membrane which surrounds it. The general organization and functioning of the protoplast presents problems of the greatest difficulty. Its appearance is constantly changing, and one hundred years ago but little was known of the cellular changes which accompany metabolic and reproductive processes. Cell membranes are somewhat more stable, and it is not surprising to find the earliest interest of botanists directed toward a more complete understanding of their microscopic structure and chemical composition.

The first observations of plant cell membrane structure antedate the recognition of the importance of the cell as an organic unit.

In 1819, Lyngbye,¹⁶⁰ a Danish clergyman, wrote the following description of a unicellular marine plant: "*Substantia membranacea, non gelatinosa, sed pro tenuitate, sub lente minutissime punctata.*" A photomicrograph of this plant cell membrane^{Fig. 3b, d} has the essential characteristics of the drawing which accompanied Lyngbye's description,^{Fig. 3a, c} and was made about a century and a quarter earlier.

Schleiden, who helped to evolve the "cell theory" in 1838, made careful studies of cell membranes as well as of protoplasts during cell membrane formation. In this connection he states:^{226, p. 237} "In the cell there is also another distinct, perfectly

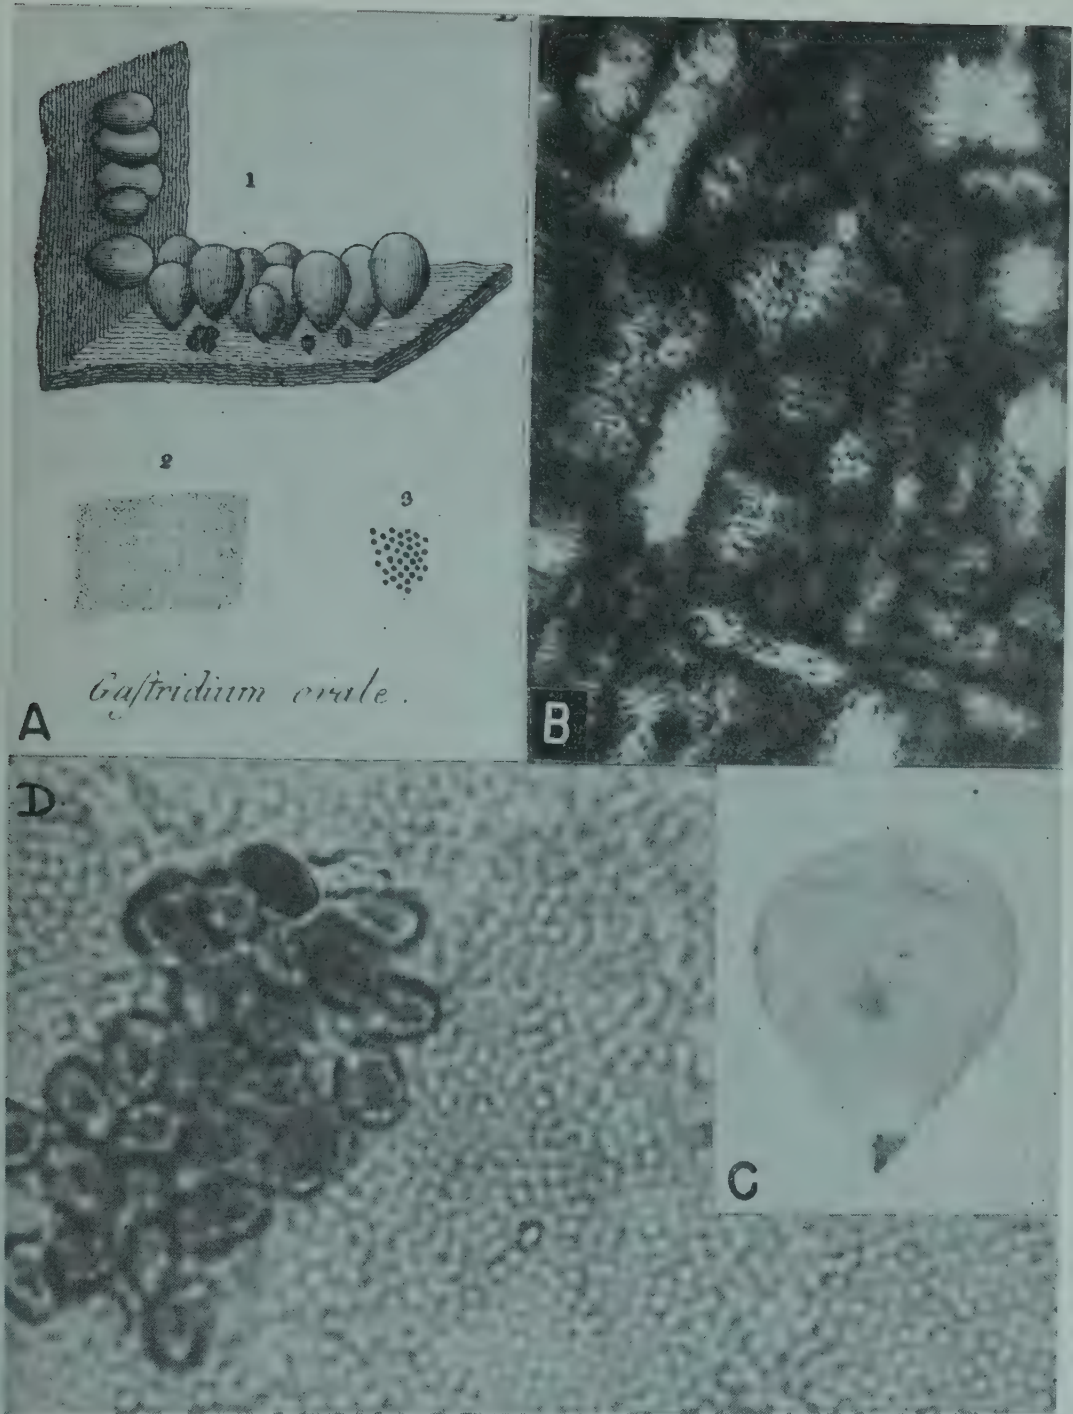

FIGURE 3. A. Copy of a plate from Lynghye (1819) showing drawing of entire plants of *Gastridium ovale* (renamed *Halicystis ovalis* in 1901) and a detailed sketch of the "minutissime punctata" in the cell membrane. B. Photomicrograph of the same cell membrane in polarized light showing patch-like orientation of doubly refractive material in the wall (X 690). C. Photograph of single plant of *Halicystis* (X 2). D. Photomicrograph of membrane structure of *Halicystis* showing cellulose particles originally described by Lynghye and chloroplasts in which the formation of cellulose particles is taking place (X 1460).

transparent substance which presents a homogeneous appearance when subjected to pressure; when dried it imbibes water and swells. For brevity's sake I shall call it vegetable gelatin, and am inclined to class under this head, as mere slight modifications, pectins and many of those substances which are usually enumerated under the term 'vegetable mucous.' It is this gelatin which is ultimately converted by new chemical changes into the actual cellular membrane, or structures of which it consists in a thickened state, and into the material of the vegetable fiber." 226, p. 244-245

"This jelly finally is converted at its outer surface into vegetable fiber, following the direction of a spiral line. . . . The unusual and altogether absolute fact at which we arrive is that these spiral fibrils are never found free, but are developed in the interior of the cells; and that the walls of these cells in the young state are simple, and generally very delicate. . . . I have reason to believe that complete consumption of the fibrils takes place in the formation of the membranes of the spiral vessels, and is the cause of their subsequently conveying only air. More frequently, however, one or more fibrils are unused; but then a great portion of the jelly has still remained unconsumed, which, when the cell is moistened with water, comes forth in the form of an intestine, and, in swelling, expands itself over the fibers."

From observations of earlier stages of protoplasmic behavior he adds: 226, p. 236

"In the further process of organization (in which process, the gum-like jelly is always the last immediately preceding fluid) a quantity of minute granules appears in it, most of which, on account of their minuteness, look like mere black points."

Likewise, von Mohl 175, p. 36 found in 1836: "If a tissue composed of young cells be left some time in alcohol, or treated with nitric or muriatic acid, a very thin, fine, granular membrane becomes detached from the inner wall of cells in the form of a closed vesicle. This membrane colors yellow with iodine."

Valentin observed at about the same time: 262, p. 237 "We see that at first a simple cell membrane exists in which there are neither spiral lines nor cross-lines. In the interior of the cell one finds a granulous substance whose particles exhibit no orderly arrangement. Later they build cross-lines, then spiral lines, in which, early in the development, one may still distinguish the discrete particles, and which finally form an unbroken continuity. In this way filaments are formed which, in some situations, have an appearance like strings of pearls, in others, on the contrary, are less sharply indented. A transformation of the cell contents thus takes place, the granules gradually disappearing; the wall of the cell at the same time becomes thicker at the expense of the protoplast."

In the studies of Payen,¹⁹⁴ particular attention was given to the chemical composition of the membranes and the protoplasts of many types of cells. He described differences between tissues which are more or less "pure" cellulose and those which contain larger proportions of "incrusting materials." In 1839 he published the rough formulas for these substances obtained from wood:

Incrusting substance: $C_{35}H_{24}O_{10}$

Cellulose: $C_{24}H_{20}O_{10}$ or $C_{24}H_{18}O_9$ plus H_2O

He found that cotton fibers contain less incrusting substance and are more easily purified than linen. He pointed out also evidence for the isomeric relationship of starch, cellulose, and dextrine, stating that these products differ among themselves only in their remarkable states of aggregation, which greatly modify their physical properties. Payen's "Mémoires"¹⁹⁵ published in 1842 contained the important information that, after extensive analyses, he had demonstrated that the membrane substances from all parts of the plant kingdom, when purified from foreign deposits, exhibit the same composition in terms of relative proportions of carbon, hydrogen, and oxygen. Purification treatments consisted in successive extractions with hydrochloric acid, ammonia, water, alcohol, and ether. Material thus prepared gave an analysis reasonably constant, isomeric with starch, and was identified by the author as cellulose. Payen also reports an experiment, "curious and easy to repeat," upon

the microscope slide which permits the recognition of the parts of the tissues which are made of cellulose, without purification. His directions are as follows: ¹⁹⁵, p. 216 " (a) Place a small amount of tissue upon a slide in a drop of water. Add two or three drops of iodine. Absorb excess with a piece of filter. A light yellow coloration is produced. (b) Add a drop of concentrated sulphuric acid and again remove excess with filter paper. The cells with which it first comes into contact begin to separate, then acquire a blue violet shade, brought about by the iodine in contact with the cellulose, which in the course of the reaction is reduced to a state of aggregation of amylaceous particles."

This microchemical method of cellulose identification has been used continually, even to the present time. Through its careful application, both alone and combined with other micro- and macrochemical treatments, Payen was able to recognize the presence of pectic substances, wax, proteins, minerals, and many other materials, in intimate association with the cellulose in plant-cell membranes of many types. In 1856 he reported ¹⁹⁶ the confirmation of these earlier findings through his own continued studies as well as those of Brongniart, de Mirbel, von Mohl, Trecul, and others. Three years later, honoring the presence of the distinguished botanist of Munich, Carl von Nägeli, he presented before the Paris Academy ¹⁹⁷ his more recent observations upon the analogies and differences between starch and cellulose. Among other reagents, the effect of cuprammonium hydroxide, recently introduced as a solvent for plant fibers by Schweizer, ²³³ was described. He pointed out that the obstacles to solution in "cuprammonium" are often the cell cuticle and the incrusting substances, and that when these are removed, dissolution of the cellulose can be effected. He had found that solutions of cellulose thus prepared, to which a slight excess of hydrochloric acid or acetic acid had been added, precipitated the cellulose in white, granular flocks. When washed with water these represented the pure elementary particles of cellulose whose division, after precipitation, he considered to be more mechanical than chemical, for not only were they insoluble in water, but iodine would not color them directly. He found, however, after treatment with an aqueous solution of slightly alcoholized iodine, which gave them a pale-yellow color, that it sufficed to touch them with sulfuric acid to bring about the blue coloration with iodine characteristic of cellulose. A more complete reaction with sulfuric acid gradually converted the cellulose granules into dextrine and sugar. Payen found also that cellulose is precipitated from cuprammonium solution not only by mineral and vegetable acids, but also by an excess of ammonia and by a large excess of water. The elementary analysis of the precipitated cellulose, made with the assistance of M. Billequin, gave "the composition of pure cellulose, $C_{12}H_{10}O_{10}$."

At a later period in this same year, Payen ¹⁹⁸ summarized for the Paris Academy his many years of fruitful research in the field of cell-membrane analysis with the following remarks: "Cellulose of the pith of underground stems and aerial stems of herbaceous and ligneous plants does not differ from that which makes up the textile fibers and other cells of plant tissues. Differences which exist between the properties of cellulose in plant organisms depend largely upon the variable degrees of its gradually accrued cohesion, and the influence of the organic substances or minerals with which it is injected or combined. Without doubt there remains much to do with respect to the precise determination of these substances in the different ligneous and herbaceous tissues. Perhaps there will be found many states truly isomeric with pure cellulose; but that demonstration, strongly interesting, without doubt, is not to date accomplished."

During this same period the question of the isomeric nature of cell-membrane constituents had been studied intensively by Fremy. ⁷¹ He had shown, over ten years earlier, ⁷⁰ that vegetable tissues contain an insoluble substance, to which he gave the name *pectose*, which accompanies the cellulose almost constantly and which, under very weak influences, is converted into soluble *pectine*. The knowledge of this con-

version was applied to the better understanding of the remarkable modifications which he saw in cell membranes during vegetative growth. In certain cases their thickness was greatly augmented; in others, greatly diminished. The latter phenomenon was illustrated by the wall of a cell of a green fruit, which is very thick and constituted of many concentric layers. At the time of maturation the membranous material in pears, *e.g.*, was found to be reduced from 17.7 parts in 100 to 3.4 parts in 100, and this alteration was indicated by the changes which the fruit undergoes in hardness and transparency.

By treating cell membranes successively with cuprammonium hydroxide, an acid, and later potassium hydroxide, Fremy⁷¹ found that cellulose, nitrogenous material, minerals, and pectic material can be identified in most plant cell membranes. He also found a substance, which he believed to be derived neither from cellulose nor from pectic material, which was soluble in water, had an acidity comparable with malic acid, was non-volatile, formed soluble compounds with all the bases, reduced salts of gold or silver with great ease, and was closely associated with the pectic material in the membrane. He named this substance *acide cellulaire*.

In a later communication, Fremy⁷² summarized his findings with the statement that the differences which one finds in the various types of cell membranes in the different parts of the vegetable kingdom are probably due to foreign materials deposited upon the surface of the cellulose, or infiltrated into its thickenings. While he could not entirely exclude the possibility that these substances in the membrane have, for a base, a body which is isomeric with cellulose, he expressed the belief that between them, at least, there are differences which are comparable to differences which exist between *albumen*, *fibrin*, and *casein*.

The physical structure of vegetable cell membranes likewise received attention from botanists and microscopists. The studies of Schleiden,²²⁶ Valentin,²⁶² and Meyen¹⁶⁷ had shown that the membranes are not built of a homogeneous substance, and that many cell membranes are distinctly fibrillar. Von Mohl¹⁷⁶ reported in 1845 that while it was clear that these cell membranes possessed a definite inner structure, it did not seem to be conclusive that they were made up of definite fibrils separated from one another. He suggested that many appearances in the fiber might be due to irregular arrangement of associated molecules in the membrane, which resulted in the easily discernible divisibility of the membrane.

After the publication of the work of J. G. Agardh,¹ von Mohl repeated this phase of his work, disproving his former conception and corroborating Agardh's findings that the fibrils of the cell membrane are distinct, separable entities and that it is therefore not possible to call them "faults." In *Confervea acraea* the lamellae of the membrane separated in a clean-cut fashion, showing no connection between the sheaths. He concluded, therefore, that the spiral fibrils do not pass from one lamella to another. He found also that the fibrils within a given lamella could be separated with needles. Schaech²²¹ likewise found that these cell membranes could be disintegrated into fibrils by either mechanical or chemical means, and showed that the fibrils, when arranged in opposite directions in the membrane, have opposite properties in polarized light. Wigand²⁶⁹ in 1856 corroborated von Mohl's conclusions that the crossing fibrils, so evident in many types of cells, belong to different layers of the cell membrane.

With full knowledge of these studies in which abundant evidence of the chemical and physical heterogeneity of plant cell membranes had been presented over a period of more than twenty years, Carl von Nägeli,^{182, 183, 184, 185} having studied cell membranes and starch grains in polarized as well as ordinary light, drew the following conclusions: (a) The presence of crystalline material in the membranes is indicated by their double refraction in polarized light; (b) these crystallites are in molecular sheaths which are parallel with the surface of the cell as well as in molecular rows which extend from the inside out; (c) in one direction they are sheaths or lamellae,

in the two other directions, the visible membrane striations; (d) both lamellation and striation are due to the alternation of "water-rich" and "water-poor" areas; (e) the dry colloid is made up of diminutive, microscopically invisible, crystalline micellae which are nearly contiguous and almost fill the space; (f) by moistening with water or aqueous fluids, the surfaces of these micellae take up water and the previously hard substance becomes soft; (g) upon evaporation the condition is reversed and the micellae again lie alongside.

Nägeli's use of the micellar hypothesis in attempts to explain various phenomena was extensive. Protoplasm, as well as the cell wall, was assumed to be made up of these fundamental units or micellae. Upon the basis of their arrangement in the protoplast there were two kinds of protoplasm, *trophoplasm* and *idioplasm*. The idioplasm was designated as the physical basis of heredity, micellae or "ids" constituting an elaborate network throughout the organism. He assumed that the hereditary characters were brought about by various types of groupings within the network. This "highly speculative"²³⁶ and "fragile"⁵⁴ *idioplasm theory* is now of historic interest only, its extreme assumptions having given way to the large accumulation of observational data associated with the cellular aspects of heredity. The continued use of the micellar hypothesis in connection with the structure of plant cell membranes has been discussed by Fischer⁶⁶ who states, "For more than thirty years I have observed each new revival of Nägeli's 'swelling theory.' The more consideration I give to the matter, the more I am impressed with the unsolvable contradictions between the well-known hypothesis and the easily observable facts."

In commenting upon disregard of the chemical heterogeneity of the plant cell membrane, such as was shown by Nägeli in the formulation of the micellar hypothesis, Branfoot^{33, p. 86} states, "... the conclusions of Braconot, Payen, Fremy, and many others were overlooked, mainly because of the widespread conviction which prevailed at that time that the cell wall was homogeneous, being constituted entirely of cellulose. The recognition of the part played by pectic compounds in plant structures was also hindered by the lack of coöperation between the botanists and chemists of the day, and by the fact that the properties and reactions of these compounds were frequently attributed to cellulose. A state of confusion was therefore inevitable, and in spite of efforts on the part of Guthowsky (1883) and Tschirch (1889), the heterogeneous character of cell membranes was not accepted until Mangin had published his valuable histological memoirs (1888-1894)."

Despite the "unsolvable contradictions" referred to by Fischer, the micellar hypothesis has served as a basis for continued speculation in relation to the structure of plant-cell membranes. An attempt to explain its widespread acceptance in the interpretation of cell-membrane structure and behavior, and its concurrent rejection in the interpretation of the phenomenon of heredity, leads one to the possible conclusion that it is due, not to the "lack of coöperation between botanists and chemists,"^{33, p. 86} but to comparatively full coöperation of botanists with chemists. In the field of chemical research the workers are accustomed to think and interpret in terms of molecular structure, and thus have been afforded an opportunity to select and emphasize those findings in botanical science which could be most conveniently correlated with their own data. As a consequence, detailed microscopic and microchemical analyses have been obscured in the development of theories of the structure of cell membranes which would account for their gross chemical behavior. In the development of the science of heredity, microscopic structural considerations have taken precedence over interest in the chemical factors involved, although the latter have not been entirely neglected. As a result, the intricate structural changes of nuclei and protoplasm, now recognized as fundamentally important in both vegetative and sexual phases of reproduction, would have little in common with the conception of "idioplasm" advanced by Nägeli.

The micellar hypothesis, as applied to cell membranes, involving the arrangement of submicroscopic cellulose micellae and water in such a way as to produce "water-rich" and "water-poor" areas, brought forth comments of various sorts from Nägeli's contemporaries. Kabsch¹⁴⁰ called attention to the presence of various "incrusting substances" closely associated with the cellulose in the cell membrane. He suggested the possibility that these associated substances are transformation products of cellulose. Hungerbühler,¹³⁵ commenting upon the chemical complexity of the membrane suggested, since the growth of cell walls occurs only in the immediate presence of proteins, that cellulose is probably a decomposition product of protein. Dippel⁵⁵ and Krabbe¹⁴⁷ could not corroborate Nägeli's findings concerning the "water-rich" and "water-poor" areas. Pfister²⁰⁰ and Müller¹⁸¹ observed that crystals of calcium oxalate from the protoplasm sometimes adhere to the inner surface of cell walls and are slowly imbedded by the deposition of new layers of cellulose. Klebs¹⁴⁵ and Noll¹⁸⁹ observed that dead protoplasmic particles became imbedded in the cell membrane in a similar manner, and Correns⁴⁶ found that, in some instances, even entire chloroplasts are to be found between the wall lamellae. Figures 4b and c illustrates two types of cell-wall inclusions.

Schnitz²²⁷ asserted that the fibrils in the cell membrane are formed from granules in the cytoplasm. Van Wisselingh²⁷⁰ and Krasser¹⁴⁸ accumulated microchemical data showing that cell membranes may contain proteins, pectins, hemicelluloses, and other materials, and that the lamellae and striae are due to chemical differences in the membrane constituents. Bowman²⁹ found that certain chemical reagents act unequally upon different parts of the cell membranes of cotton fibers, some portions of which were more readily soluble than others. He concluded^{p. 67} that "No cotton fiber is ever perfectly pure cellulose . . . it is probable that on the average there is not more than 87 per cent of pure cellulose." He states,^{p. 72} "If a quantity of cotton fiber be subjected to boiling acid for some time, and then dried, it can be rubbed into a fine powder which, under the microscope, exhibits all the features of mechanical and scarcely any chemical disintegration. It seems indeed as if the action were exerted not upon the pure cellulose itself, but upon the various foreign matters which are associated with it in the fiber wall." Again,^{p. 64} "Some chemists have supposed that water uptake depends entirely upon the tubular or cellular structure of the fiber so that it is only an instance of capillary attraction; but the fact that if we precipitate the cellulose from its solution in ammonia-cupric oxide solvent, the amorphous jelly which has no capillary structure also possesses this same property, militates against this view."

Although these various workers had approached the problem of cell-membrane structure and composition from many different angles, one gathers that their chief difficulty in adopting the micellar hypothesis rested in its conception of chemical homogeneity of the membrane. The greater number experienced no difficulty in demonstrating the presence of crystalline material in the membrane by means of polarized light, and shared with Nägeli the inability to distinguish smaller microscopic structures than the *fibrils* or *striae*. Their microchemical studies, however, showed a chemical composition of the cell membrane more complex than the cellulose-and-water postulated by Nägeli. Although Russow,²¹⁵ Berthold,²⁵ and Terletzki²⁵⁶ added further information concerning this chemical heterogeneity, the more comprehensive studies in this connection were those of Tschirch²⁶¹ and Mangin.^{162, 163} Together these compilations, published shortly before 1890, constituted a fitting close to the half-century of microchemical work which had opened with the researches of Payen¹⁹⁸ and Fremy.⁷⁰ Mangin found *lignin*, *suberin*, and other substances in intimate association with the cellulose in many cell membranes which he examined microchemically. A neutral, insoluble substance of pectic nature was invariably present, for which he suggested the name "pectose", on the assumption that it was composed of pectin in combination with cellulose. He found difficulty, however, in

determining the chemical properties of pectose, although microchemically it was distinct from cellulose in its color reactions, behavior toward acids and alkalis, polarized light, and Schweizer's reagent. Mangin concluded that pectose exists in cell membranes along with cellulose from the earliest stages of formation of the

FIGURE 4. A. Disintegration of a cotton fiber into fibrils and *dermatosomes* (after Wiesner). B. Crystals imbedded in the cell membrane of *Allium cepa* (after Molisch). C. Chloroplasts between the lamellae of the cell wall of *Valonia* (after Correns).

membrane. He also suggested that various phenomena associated with cell-wall modifications, such as *gelatinization*, *cutinization*, and *liquefaction* are due to pectose transformation.

Nägeli's inability to discern microscopic structure in the cell membrane below that of the lamellae and striae led to his conception of the submicroscopic nature of the *micellae*. This was in disagreement with the observations of Lyngbye,¹⁶⁰ Valentin,²⁰² Schleiden,²²⁸ and others who had preceded Nägeli in this field of research.

Strasburger,²⁵⁴ after an intensive study of the swelling behavior of mature cell membranes and of the living protoplast during cell-membrane formation, reported that in cells, in which the wall thickening had not yet begun, *microsomes* were distributed at random in the protoplasm. Later on, when there was scarcely a trace of thickening in the wall, the microsomes showed an orderly arrangement in the outer region of the protoplast. He found that this arrangement was sometimes in the form of a spiral which corresponded to the spiral fibrils of the mature wall. In the regions of active wall-thickening the microsomes were quickly used up as they were deposited in successive layers to form the cell membrane:^{p. 80} "The final membrane structure produced is similar to a net, the microsomes corresponding to the mesh and not to the lattice."

Strasburger's attempts to determine the chemical nature of the microsomes led to the conclusion that, since they stain yellow with iodine, they are presumably *protein*. A careful comparison of the results of Strasburger with those of the earlier workers shows clearly that the microsomes whose presence and behavior he observed are identical with the "*minutissime punctata*" of Lyngbye,¹⁶⁰ the "*granula minuta*" of Link,¹⁵⁷ the "spheroids" of Agardh,¹ the "ellipsoidal or spherical granules" of Kützing,¹⁵² the "granules" of Valentin,²⁶² and the "membrane granules" of von Mohl.¹⁷⁶ These observations were concerned chiefly with the membrane structure, and the results differed with those of Nägeli in that they showed, in the course of the formation of cell-membrane lamellae, the deposition of microscopically visible granules from the protoplasm, instead of the intercalation or deposition of submicroscopic *micellae*.

In 1886, Wiesner²⁶⁸ corroborated Strasburger's findings and suggested that the name *microsomes* be changed to *dermatosomes* because of the important role played by these granular structures in building up the cell membrane. He concluded that the cell membrane is an aggregate of granules or dermatosomes, between which is binding material, and that the dermatosomes are protein while in the cytoplasm, but turn into cellulose after they have been oriented and deposited in the cell wall. The binding substance he believed to be only partially converted into cellulose at the same time. In the mature membranes he found the dermatosomes arranged to form fibrillae, or merely sheaths, through the function of the binding material. By treatment with hydrochloric acid, he succeeded in reversing the process of formation and bringing about the separation of the membrane into lamellae, and the lamellae, in turn, into dermatosomes or into fibrillae composed of single rows of dermatosomes (Fig. 4a).

In 1889, Palladin¹⁹³ observed that the growth of cell walls and the formation of starch grains take place only in the immediate presence of proteins or leucoplasts. He concluded that starch and cellulose appear to be transformation products of proteins. This transformation, according to Palladin, takes place in the protoplasm, not after deposition in the cell membrane, as had been supposed by Wiesner.²⁶⁸

Schulze and co-workers,^{229, 230} upon the basis of extensive chemical investigations of cell membrane constituents, classified them roughly into two groups: the *hemicelluloses*, which can be extracted by 1 per cent HCl or H₂SO₄ and, upon hydrolysis, yield *galactose*; and *true cellulose* which is not soluble in 1 per cent acid and, upon hydrolysis, yields *glucose*. Their detailed analyses revealed the presence, in plant-cell membranes, of hydrates of carbon of many different types. They reserved the name *cellulose* for the particular membrane components, which dissolved in cuprammonium hydroxide, were not attacked by weak acids, and were colored blue with sulfuric acid and iodine and with chlor-zinc-iodide. They emphasized the amorphous nature of cellulose and sometimes designated it as an uncrystallizable body.

Behrens'²² "The Microscope in Botany," along with treatises by Tschirch²⁶¹ and Reiss,²⁰⁷ expresses clearly the state of confusion concerning the structure and chemical composition of plant-cell membranes which existed at the beginning of the

last decade of the nineteenth century. As Gilson explained in 1893:⁸⁶ p. 397 "Certain workers believed that the membrane consists of cellulose, a single substance which was itself a chemical individual; others believed that the membrane consisted of many physical modifications of cellulose; still others designated under the name cellulose substances which were very different chemically."

Few workers who used the microscope in the course of their investigations failed to observe the double refraction of most cell membranes in polarized light. They were thus convinced of the presence of crystalline material and, as had Nägeli, associated this double refraction with the cellulose component. The fact remained, however, that even membranes composed largely of cellulose, as shown by both chemical and microchemical reactions, displayed typical *colloidal* behavior when treated with reagents of many types. Swelling reactions thus produced were often completely reversible, but the phenomena were so striking that such workers as Schulze and his associates were led to emphasize the amorphous nature of cellulose itself.

Gilson⁸⁶ was concerned with the growing belief in the amorphous nature of cellulose and attempted to obtain pure crystalline cellulose from its solution in cuprammonium hydroxide. He hoped, in the course of his investigations, to settle the following points: (a) Which of the carbohydrates is it that crystallizes from a solution of the material of vegetable tissue in Schweizer's reagent, when strong ammonia is added? (b) Is cellulose a distinct chemical individual, or are there several compounds in the cell wall that are insoluble in dilute acids and alkalis, and give the blue color with the iodine reagents? (c) Is the cellulose free or in combination in the cell membrane with other constituents? (d) Is the cellulose distributed through all three layers of the cell membrane or localized in certain parts?

Moderately thick sections of the swollen root of *Beta vulgaris* were soaked in 1 per cent KOH (or eau de javèlle) to dissolve out the cell contents. The sections were then washed with distilled water and placed in Schweizer's reagent for 4 to 5 hours. The dissolved cellulose was precipitated in crystalline form by putting the sections into ammonia, after removal from Schweizer's reagent. The size of the crystals were said to vary with the strength of the ammonia, 5 per cent giving only sphero-crystals, and 20 per cent giving beautiful arborescent or radially arranged, spicular crystals. The crystals could be seen best after clearing the sections of copper compounds by washing them with water, treating them with dilute HCl, and then coloring them with chlor-iodide of zinc (or Congo red before treatment with HCl). The crystals were formed in the cell membrane and within the cell cavity. If Schweizer's reagent acted long enough, no evidence of the cellulose remained in the cell membrane, the only blue-coloring substance being the crystals within the cell cavity.

From these studies of the tissue of *Beta vulgaris* and fifty other plants from various parts of the plant kingdom, in which all except the fungi gave satisfactory crystals of cellulose, Gilson⁸⁶ concluded that: (a) the crystals precipitated from solution in cuprammonium hydroxide by the addition of strong ammonia are pure cellulose; (b) all that portion of the cell wall that is colored blue by chlor-zinc-iodide, and that portion only, goes to make up the crystals; (c) all cell walls of tissues contain cellulose, but while the internal layer consists almost entirely of it, the intermediate layer has only a small portion, and the intercellular layer only a trace; (d) the cellulose is found crystallized within the cell, showing that its solution in Schweizer's reagent is not very diffusible and gives additional proof that it is derived from the inner layers of the cell wall.

Johnson¹³⁹ repeated and corroborated Gilson's work. The crystalline cellulose was readily obtained in cells of *Beta*, *Dahlia*, *Lactuca*, *Typha*, *Ceratozamia*, *Equisetum*, and *Chara*. He found that, after keeping sections of the beet in Schweizer's fluid for 20 days, the crystals were as plentiful in the cells as at first, and concluded

that their solution in cuprammonium resembles a non-crystalline colloidal substance, which will not diffuse, rather than a crystalline one. In no instance was either Gilson or Johnson able to observe the double refraction of the precipitated cellulose in polarized light. Because of this, Gilson had called them "crystallites," not crystals. Upon the basis of this optical behavior, it was assumed that the crystalline cellulose precipitated from solution in cuprammonium hydroxide had lost its original power of double refraction. In spite of these minor differences, however, the work of both Gilson and Johnson contributed further evidence to the crystalline nature of the cellulose component of the membrane and to the function of cuprammonium hydroxide as a true solvent for cellulose.

Ambrohn and co-workers^{3, 5, 7} contributed even more important confirmation of the crystalline nature of cellulose in cell membranes by their detailed studies of orientation which extended from 1892 to 1926. They showed conclusively that the long axes of the cellulose crystallites are arranged parallel to the long axis of the fibril in the membrane, and are not necessarily parallel to the long axis of the fibril itself. Their publications have furnished an abundance of carefully prepared data in this field of optical behavior. Finer subdivisions of these fibrils themselves were not visible to him and he based his interpretation, therefore, upon the assumption that the fibrils are composed of submicroscopic crystalline micellae, in the exact sense of Nägeli.

Concurrently Mangin¹⁶³ pointed out that pectic substances occurring in the cell wall proper and in the middle lamella are not identical, and that decomposition of one by chemical, bacterial, or fungal agencies does not necessarily involve the decomposition of the other. Strasburger,²⁵⁵ through further study, had found that cell membranes have both solid and gel-like constituents, the latter in the form of a reticular, colloidal framework. Growth in area he found to be accomplished by the stretching of this colloidal framework; growth in thickness by the deposition of layers of new material composed of *gel* and *microsomes*; Molisch¹⁷⁸ found that Wiesner's *dermatosomes* (Strasburger's microsomes) are connected by fine fibrils of protoplasm; while Guthowsky⁹⁸ and Tschirch,²⁶¹ in bringing about the macrochemical separation of cell-membrane constituents, found that the removal of masses of colloidal material brings about cell-membrane disintegration.

The nineteenth century thus came to a close with a record of remarkable achievement in the field of plant-cell membrane analysis. The formation, structure, and chemical composition of membranes from all parts of the plant kingdom had received careful consideration from botanists and chemists alike. Differences of opinion which arose can be attributed largely to the types of techniques used, rather than true contradictions in the data obtained. The important consideration resulting from the review of the work of this period is that all opinions, based upon accurate observations and measurements, contributed something to the understanding of the properties of plant-cell membranes of various types.

In the list of these many contributions the name of Count Hilaire de Chardonnet³⁹ holds a place of singular importance. In 1885 he obtained a British patent covering the first successful commercial process for the preparation of artificial silk. The product is prepared from nitrated plant fibers dissolved under pressure in a mixture of alcohol and ether. The solution is coagulated by passage through water and subsequently denitrated by a treatment with dilute nitric acid, chloride of iron, and ammonium phosphate. The product is a glossy, flexible fiber, possessing many of the properties of silk, and represents the fulfillment of Hooke's¹³³ prophecy of 1665 (Fig. 2).

Chardonnet's achievement marks the beginning of a new era in plant-cell membrane analysis. The impetus which it gave to research in this field is probably beyond measure. The first quarter of the twentieth century saw the gradual shifting

of the burden of the experimental work from botanical and chemical to industrial laboratories. In these new surroundings, predominately chemical, new terminologies were to be developed and new theories to be evolved. Interest in the microscopic structural properties of the membrane was to be superseded by interest in their gross physical-chemical behavior. As observed by the nineteenth-century workers, these reactions are consistently colloidal, and from measurements of these colloidal properties entirely new conceptions of membrane structure and composition have been deduced.

The data which were collected during the nineteenth century concerning the formation and structure of plant-cell membranes are of interest, therefore, to biologists and industrialists alike. The biologist is concerned with their relation to the growth and development of living organisms; the industrialist, with their behavior during the different stages of the manufacturing processes in which they are involved. The biologist works with many types of cell membranes involving the widest ranges of structure and composition; the industrialist works with comparatively few, highly differentiated cells such as the cotton fiber, flax fiber, and wood fiber. The biologist brings to his laboratory some knowledge of the stages of development of the membranes which he studies; the industrialist is usually familiar with them in their mature, differentiated states. The biologist is primarily interested in membrane structure as related to factors such as absorption and semi-permeability; the industrialist in the gross physical behavior of the membrane in its natural, swollen, or completely dispersed state. These considerations are of importance in any attempt to follow the trends of cell-membrane research in the present century.

From the biological viewpoint, the formation of *cellulose* in the protoplasm of a living cell and its final deposition in the wall of the cell are only special aspects of two complex phenomena—carbohydrate synthesis and cellular differentiation. Priestley²⁰³ discovered in 1772 that green plants growing in an atmosphere rich in “fixed air” (carbon dioxide) produce, after a time, quantities of dephlogisticated air (oxygen). Ingen-Housz¹³⁶ reported a few years later that this production of oxygen takes place *only* in green plants and in the presence of sunlight. De Saussure,²¹⁹ in a comprehensive treatise published in 1804, showed that hydrogen and oxygen, from water, and carbon dioxide are fixed simultaneously in the green tissues in the presence of sunlight and that an increase in the weight of the plant results. He also found that normal development of the plant involved the absorption of nitrates and mineral substances from the soil.

The recognition of the cell as the unit of structure of both plants²²⁶ and animals²³² shifted the search for the “seat” of this synthetic phenomenon from the organism as a whole to the separate cells of which it is composed. Microscopic studies of the cells of both plant and animal tissues revealed the presence, in the green tissues of plants, of a structure not found in the animal cells—a green *plastid*. Although in cells from the lower part of the plant kingdom these plastids sometimes assume unusual shapes and sizes, in cells of the higher plants they are commonly disc-shaped, fairly numerous, and located in the outer regions of the protoplasm where the maximum amount of light is available. The pigment, chlorophyll, contained in the plastid, absorbs the radiant energy for carbohydrate synthesis and gives to the plant its green color. One of the carbohydrates first found in these chloroplasts is sugar, but von Mohl¹⁷⁷ revealed as early as 1837 that starch grains are also to be found in chloroplasts. The significance of von Mohl’s observation was not recognized until the more comprehensive studies of Sachs,^{216, 217, 218} Schimper,^{223, 224, 225} and Meyer^{168, 169, 170, 171} had been completed. Sachs was the first to find that the appropriation of carbon dioxide and the separation of oxygen takes place in the chloroplast, and that during the process a carbohydrate as well as free oxygen is produced. He also realized that the formation of carbohydrates represents an early

stage in the formation of proteins and other more complex organic materials. The name *photosynthesis* was applied to the process by Hansen as related by Barnes¹⁸ in 1898.

Studies of the structure, composition, and methods of formation of plant-cell membranes played an important role in bringing about a clearer understanding of the more general aspects of photosynthesis. The chemical processes involved require energy which the living cell obtains from light. Evidences of adaptation to the utilization of this source of energy are to be found in almost every green plant. If, for example, the cells of a tree, above its roots, were arranged in the form of a sphere, it would be able to produce very little food, since the light rays could reach only the cells near the surface. The tree increases its effective light-receiving area many thousand-fold by bearing high above the ground, upon its strong, tapering trunk, branches which, in turn, bear thousands of fan-like leaves. The cells of the leaves are thus held in positions in which they are able to receive sufficient sunlight to carry on their usual production of food materials from substances provided by the air and soil. The strength and rigidity necessary to maintain such a structure (sometimes hundreds of feet above the surface of the earth) could not be produced either with sugar, which is usually in solution in the cell, or with soft, loose granules of starch into which some of the sugar is transformed and stored as reserve food. Other portions of the sugar are converted, therefore, into more durable cellulose, which is used, for the most part, in the construction of sturdy walls around the cells.

The requirements placed upon these cell walls by the living organisms, of which they are a part, are exacting. When young, they must have sufficient plasticity to permit cell enlargement in one or more directions. As the cell matures they usually become more rigid. In all stages of development they must be somewhat flexible, must permit the transportation of dissolved substances to and from the protoplast and, in the food elaborating regions, at least, must be translucent. The cell walls of the tree leaf meet these requirements, as shown in Fig. 5. Fiber cells, such as those which grow upon the cotton seed, and bast or wood fibers, which are produced abundantly in stems of many of the higher plants, do not carry on the primary carbohydrate synthesis. Sugar, which is translocated from the green tissues of the plants in which it is formed, is converted largely into cellulose by the protoplasts of these cells and is used up in the construction of the thick, fiber cell walls. In the mature cotton fiber the proportion of cellulose to other cell-membrane constituents is great, amounting, in different varieties, to from 80 per cent to 90 per cent of the total mass. In mature wood and bast fibers the proportion of cellulose is much less, sometimes being reduced to from 40 per cent to 50 per cent of the wall substance. This comparatively high proportion of cellulose, as compared with the cellulose content of cell membranes in general, has led, however, to a synonymous use of such terms as *cotton fibers*, *linen fibers*, *spruce wood*, and *cellulose*. Properties of these fiber masses are commonly referred to as properties of "*cellulose*."

Some of the characteristics of cell membranes which have come to have singular industrial importance first functioned in the development of the living cell. From this viewpoint the transformation of a mass of dried fibers into a continuous plastic matrix is a form of a reversible reaction reminiscent of the time when each fiber membrane itself was capable of easy deformation. Many of the reactions which bring about this change in physical state of the mature cell membranes are currently described as "cellulose derivative formations." At the opening of the present century these reactions were the subject of considerable thought and discussion. Representative of the current thought of the time was the paper presented before the Society of Chemical Industry by de Mosenthal.¹⁸⁰ His studies had covered the microscopic structure of raw cotton and the microscopic properties of cotton fibers which had been transformed into a plastic mass either by the usual methods of nitration or by treatment with cuprammonium hydroxide. He found evidence of an

outer and inner membrane in the nitrated fiber wall. Between these membranes he found the "intercuticular" substance which appeared to constitute 85 per cent to 90 per cent of the fiber. In an illustration showing a longitudinal section of the fiber this substance is shown to consist of nearly uniform granules about one micron in

FIGURE 5. A. Young maple leaf showing the venation system which serves the dual purpose of strengthening and conducting water to the leaf cells where photosynthesis is in progress. B. Cells from a maple leaf taken from a maple seed, before germination, showing green chloroplasts in place in the outer regions of the protoplasm.

size:^{p. 292} "The intercuticular granules lie closely packed, kept in position by the cuticles, and it is only when the tension of these is sufficiently relaxed that the granules can escape."

De Mosenthal found that nitration produced little visible change in the cotton fiber. The outer cuticle wrinkled, but the intercuticular matter remained unchanged. The granules appeared to be somewhat larger, but he pointed out that this was dif-

ficult to verify through measurement. If a "solution" of the nitrated cotton were allowed to evaporate upon a glass slide, the resulting film appeared granular under the microscope, the individual granules being about one micron in size. He found a difference between the cotton regained from solutions of ZnCl_2 or $\text{ZnCl}_2 + \text{HCl}$ as compared with that which had been treated with cuprammonium hydroxide. In the former the granules were destroyed, in the latter they were preserved: p. 293 "Microscopic examination shows the granules freed and washed out as the cuticles yield to the swelling of the fiber." De Mosenthal inquires: p. 295 "Are we to regard these solutions as colloids, as suspensoids of the finely divided particles? The microscopic examination of films and precipitates certainly points in that direction. That no particles can be seen in the liquid does not militate, I think, against that view. According to Lottermoser, particles must be smaller than 0.5 micron to be microscopically invisible in solution and our particles are much larger. But surely the detection of minute particles in a liquid does not only depend upon their size, but also on the relative refractive index of the suspended matter and the liquid." During the discussion of de Mosenthal's paper the Chairman remarked that they had been wrong from the beginning in treating cellulose as a chemical entity; that it is a complicated substance; and that cellulose from various sources behaves very differently. De Mosenthal closed the discussion with the statement that the members had discussed *cellulose*, while he had discussed *cotton*. There is little doubt that he recognized their failure to regard the fiber as an organic unit, designed to meet biological requirements according to a microscopic plan which had been observed by Valentin,²⁰² Lyngbye,¹⁶⁰ Link,¹⁵⁷ Agardh,¹ Strasburger,²⁵⁵ Wiesner,²⁶⁸ and others, as well as himself. Since his interest was focussed upon the colloid behavior of treated fibers and his methods of approach primarily chemical, he probably was not aware of the concurrent interest of plant physiologists in the microscopic structure and behavior of living cell membranes.¹⁹⁹

Contemporary publications showed the effect of the impetus to research in the field of cell-membrane structure and composition which had been given by the nineteenth-century investigators. In 1901, Allen² published upon the origin and nature of the middle lamella. One of the few general reviews of the botanical aspects of cell-membrane structure was contributed by Gaucher⁸³ in 1904. Remec,²⁰⁹ Herzog,^{114, 113} and Behrens²¹ extended the studies of fiber structure by means of polarized light. Tröndle²⁶⁰ made a detailed microchemical study of the cell membrane of *Spirogyra*. Gaidukov⁸² reported advances in the use of the ultramicroscope and the microspectral photometer. Lester¹⁵⁵ extracted a "brown hygroscopic substance" from American cotton with water. Herzog¹¹³ counted twenty-eight concentric layers in a fiber wall which had been swollen with cuprammonium hydroxide. Bowman²⁹ and Flatters⁶⁷ discussed various developmental aspects of cotton fibers, and Hanusek¹⁰⁴ summarized the microscopic properties of fibers which were of importance to the rapidly growing textile industries. He comments: ^{104, p. 61} "Like all epidermal cells, cotton hairs are covered with an exceedingly thin, structureless cuticle which is insoluble in cuprammonia. The presence of cuticle serves to distinguish cotton from all bast fibers. On the inner surface of the cuticle are fine granules and striations which are particularly conspicuous when the fibers are examined after immersion in dilute ammonia water." In 1903 a treatise by Ewart⁵⁶ "On the Physics and Physiology of Protoplasmic Streaming in Plants" appeared in the Oxford Press and is worthy of mention here because of the more recent considerations of the influence of protoplasmic streaming upon the deposition of materials from the protoplasm.^{188, 285}

During the second decade of the twentieth century the need for a better understanding of fibrous materials, particularly with respect to their reactions to dyes and swelling agents, led to numerous studies of their chemical composition. Schunck²⁸¹ had found in 1868 that less than 0.5 per cent of the substances other than cellulose

were contained in unbleached cotton yarn. From this small amount of material he had identified cotton wax, margaric acid, alcohol-soluble material, alcohol-insoluble material, pectic acid, and albuminous matter. In 1915 Levine¹⁵⁶ obtained results of chemical analyses at different stages of fiber development showing much larger quantities of non-cellulosic material. Fats and waxes alone amounted to 2.2 per cent, and protein to 0.18 per cent. In 1918 Knecht and Hall stated:^{146, p. 220} "Since the amount of impurities in raw cotton was known to be at least ten times greater than that accounted for by Schunck, and it was considered that prolonged boiling with alkali might bring about more or less drastic changes in them, it was decided to proceed as far as possible by way of systematic extraction with purely mechanical solvents." By these methods of extraction the amount of "impurities" found in American cotton totaled 4.327 per cent and in Egyptian cotton 4.124 per cent. The alcoholic extract (0.533 to 0.744 per cent) was an amorphous, brown, very hygroscopic, faintly acid substance containing as much as 43.4 per cent of ash and exerting a powerful reducing action on Fehling's solution. The aqueous extract (1.509 to 1.656 per cent) was likewise amorphous and brown, slightly less hygroscopic, and less effective in reducing Fehling's solution. This extract was also faintly acid and contained as much as 54.5 per cent of ash. The lime extract (2.1 per cent) was found to consist of protein, pectic acid, and fatty acid, as well as two resinous substances. A contemporary report upon the physical and chemical properties was made by Harrison.¹⁰⁵ Studies carried out by Minaev¹⁷³ upon developing cotton fibers showed that in the membranes 5-day fibers contained no cellulose deposits; 10-day fibers assumed a violet coloration with chlor-zinc-iodide; 20-day fibers contained cellulose in abundant amounts.

A paper announcing the existence of daily growth rings in the cell walls of cotton fibers was published by Balls¹⁷ in 1919. Egyptian cotton of different stages of development preserved for five years in 30 per cent alcoholic solutions of glacial acetic acid were not sufficiently swollen to make clear the lamellate structure of the wall. Therefore, the Cross and Bevan⁴⁸ method involving treatment with sodium hydroxide and carbon disulfide was used; this enabled him, through correlations with climatological data, to draw the following conclusions: (a) the primary wall of seed hairs in cotton contain very small amounts of cellulose; (b) secondary thickening of the wall proceeds intermittently under normal Egyptian field conditions, being arrested every afternoon; (c) the cellulose of the hair consequently consists of a number of concentric shells, layers, or growth rings, each one representing one day's growth, with the exception of the primary wall; (d) counts of rings in the lint could never be proved to exceed 25; the smallest figure obtained was 20; (e) secondary thickening begins in the wall on the 21st to 25th day and continues until 25 daily depositions have taken place; (f) the thickness of each of the 25 "growth rings" can only be about 0.4 micron; (g) the hairs are covered outside the cellulose wall by a cuticle, bearing wax, which is structurally and historically identical with the cuticle of the testa; (h) the secondary wall, but not the primary wall (cuticle) is traversed obliquely to the axis by simple pits which are rarely visible except in the living hair, and to these pits is due the twisting of the hair and its characteristic convolutions after death.

Reissek²⁰⁸ in 1852 had observed the wall "lamellae" in cotton fibers and shows in his illustrations at least nine, in longitudinal view. About the same time, Crum⁵⁰ cross-sectioned the fibers, and made drawings showing four and five concentric layers. Butterworth³⁶ and Minajeff¹⁷⁴ had also preceded Balls in the study of cross-sections of fibers; and Herzog,¹¹⁶ five years earlier, had reported as many as 28 lamellae in the cotton-fiber wall after it had been swollen with cuprammonium hydroxide. Balls made the first attempt to correlate the lamellate depositions in the wall with a daily periodicity. His original premises were that no cellulose is deposited in the wall until after 20 days of fiber development and that during the re-

maining 20 to 25 days of fiber growth, one layer is deposited every day. More recent studies, to be described later, have shown the presence of cellulose in the protoplasts of 1-day fibers and its lamellate deposition in the walls of 3- to 5-day fibers. These observations have called for drastic alterations in Balls' original premises. With the total period of fiber development covering approximately 50 days, there is needed almost double the number of "daily growth rings" postulated by Balls.

A few of the many papers which are representative of the cell-membrane studies of this period are those published between 1909 and 1920 by A. Herzog^{113, 114, 115, 116, 117} and Harrison.^{105, 106} Their studies included microscopic observations in both ordinary and polarized light and reactions in cupraunonium hydroxide and other swelling agents. The effects of mechanical treatments were described by Cross and Bevan,⁴⁷ who found that cotton rope used for power transmission was converted, at the core, into rounded, hyaline masses of small dimensions; thus the "fibrous colloid had been transformed through a phase of hydrate fusion into the structureless form in question." Fort,⁶⁸ who followed the breakdown of cotton fabrics under "beetling" treatment, reported that a "powder" of cellulose was obtained which was soluble in alkali and possessed microscopic features different from "shredded" fabric. The importance of the colloidal properties of various types of cell membranes, emphasized earlier in the work of Chardonnet,³⁹ was evidenced anew in the work of Ost,¹⁹² Gibson, Spencer, and McCall,⁸⁵ Wheeler,²⁶⁴ and Schorger.²²³ Among the books of the period destined to play an important part in stimulating and shaping investigations of the future were "The Textile Fibers" by Matthews,¹⁶⁶ "Researches on Cellulose" by Cross and Bevan,⁴⁸ "Researches on Cellulose. IV," by Cross and Dorée,⁴⁹ "Mikrochemie der Pflanzen" by Molisch,¹⁷⁹ and "Biochemie der Pflanzen" by Czapek.⁵¹ Botanical researches dealing with cell-membrane structure and composition carried on during the first quarter of the present century are summarized by Sharp^{236, p. 218} as follows: "As a general rule, the primary layer seems to be largely pectose, the secondary and tertiary layers being made up of cellulose together with pectose and other materials. It is only rarely, however, that pectose and cellulose exist in anything approaching the pure form. The pectose of the middle lamella soon changes to insoluble pectates, chiefly that of calcium, while the other layers become greatly altered in composition by chemical transformation and the addition of new materials. A certain amount of protein matter seems to be present in all the layers. In the apical meristems of *Vicia faba* Tupper-Carey and Priestley (1923) find the middle lamella to be probably a mixture of pectin and protein and that the thickened walls, although they all contain cellulose, may not react as cellulose because of the presence of proteins and other substances. . . . The presence of proteins is noteworthy in connection with the question of the relation of the protoplast to the wall."

The investigations upon which these conclusions are based are thoroughly reviewed in the writings of Czapek,⁵¹ Molisch,¹⁷⁹ Gleisberg,⁸⁷ Grafe,^{89, 90} van Wisselingh,²⁷¹ and Hansteen-Cranmer.^{100, 101, 102, 103} The last author, in a series of investigations of the toxic effects of K, Na, and Mg ions on root growth, found that the toxic effect was due to changes produced in the cell walls and not in the cell protoplasm. In the course of subsequent investigations, the cell walls were found to contain lipoid substances, and walls of all living plant cells to contain comparatively large amounts of phosphatides. Grafe^{91, 92} and Grafe and Magistris⁹³ corroborated these findings. Hansteen-Cranmer,¹⁰² unable to find any break in the continuity of phosphatides in the protoplasm and the wall of a cell, developed the conception that the wall as well as the protoplast is a living structure. Kissel¹⁴⁴ studied the relation of *cutin* to *cellulose* in cell membranes; van Wisselingh²⁷¹ demonstrated an intimate relation between *suberin* and *cellulose*; and Anderson^{8, 9} showed that in collenchyma cell walls there is an alternation of pectic and cellulose

lamellae; he demonstrated an intimate relation between *cellulose*, *pectic material*, and *cutin* in the epidermal cell walls of *Clivia nobilis*. He concluded,^{9, p. 312} "From the standpoint of microscopic structure, the wall is a complex of several chemically different lamellae. The lamellae may consist of one chemical substance, and alternate with lamellae of other cell wall constituents, or the various constituents may be present in the same lamellae."

The chemical heterogeneity of cell membranes, thus evidenced at all stages of their development, constituted the basis for the rejection of the concept of chemical homogeneity as advanced by Nägeli in the micellar hypothesis. The inadequacy of the conception of a structure composed of crystallites separated by films of water was commented upon at length by Fischer⁶⁶ in 1927, who pointed out that the phenomena of dyeing, swelling, and semi-permeability are not explainable upon the basis of the membrane structure proposed by Nägeli.

From the standpoint of the presence of crystalline cellulose in the cell membrane, Nägeli's hypothesis received, in the meantime, excellent corroboration. The extensive researches of Ambrohn,⁵ Ambrohn and Frey,⁶ and Frey,^{79, 77, 78} by means of polarized light, led to the following conclusions: (1) by optical methods with the help of double refraction one can find that there are present in the cell membrane distinct cellulose micellae which must have an elongated form; they are strongly anisotropic and behave optically as a rhomboid crystal which shows the main refractive indices n_γ , n_β , n_α ; n_β is only weakly differentiated from n_α and, upon the basis of many measurements, the values $n_\gamma = 1.594$ and $n_\beta \sim n_\alpha = 1.533$ were obtained; (2) the micellae themselves are doubly refractive and this property permits detailed studies of their orientation in polarized light (Fig. 6a to d) [Ambrohn's previous work⁴ with "Stabchendoppelbrechung" and "Eigendoppelbrechung" provided information which was used in checking the nature of the double refraction produced by the cellulose micellae]; (3) the cellulose micellae possess normal dispersion of the double refraction and permit the passage of ultraviolet light. Cutin does not permit the passage of ultraviolet light and this method of study is valuable in differentiating these two membrane components; (4) the relative positions of cellulose, cutin, pectin, and lignin in the cell membrane were determined by means of observations involving both polarized and ultraviolet light; (5) the theory of Nägeli that the cell membrane is built of long, submicroscopic, optically anisotropic, crystalline micellae is valid.

The crystalline nature of the cellulose constituent of cell membranes received additional confirmation from the studies made by means of the newly developed technique, x-ray diffraction analysis. The methods described by Laue,¹⁵³ Bragg,³² and Debye and Scherrer⁵³ were quickly adapted to the study of cell membranes and, as early as 1913, Nishikawa and Ono¹⁸⁸ had obtained symmetrical diffraction patterns from wood fibers and bamboo. Scherrer²²² corroborated these findings in 1920 and more complete confirmation was provided in a series of studies by R. O. Herzog and co-workers^{124, 118, 119, 123, 122, 121} between 1920 and 1926. Herzog studied both untreated and treated fibrous materials in swollen and unswollen states, with and without tension. The definite crystalline nature of cellulose was thus established and, in addition, the significant point that cellulose from various sources in the plant kingdom produces the same x-ray diffraction pattern. From comparisons of many diffraction patterns Herzog pointed out that the results of x-ray diffraction analysis confirmed the detailed studies of fibers in polarized light; that the cell walls are made up of fibrillae which, in turn, are made up of a number of parallel crystallite chains; and that the crystallite is the unit revealed by x-rays. He believed that the fibrillar structure is the result of tension developed in the living fiber during growth and that the $C_6H_{10}O_5$ groups are linked together according to Werner's theory of secondary valence. Microscopic studies of colloidal materials reported by Freundlich and co-workers^{75, 76} during the same period furnished information which has

proved to be helpful in attempts to correlate data obtained by means of x-rays and the microscope in dark field, and in ordinary and polarized light.

These various physical measurements of cell membranes which had served to establish the crystalline nature of their cellulose component had also contributed further evidence toward their chemical heterogeneity. Even the x-ray diffraction patterns bore evidence of amorphous material in addition to the cellulose crystallites. Herzog¹²⁰ in 1925 described its relation to the cellulose crystallites as an "imbedding substance." Anderson^{9, p. 306} pointed out in this connection in 1928: "These facts have made necessary a modification of the original Nägeli theory. It is highly probable that the spaces between the micellae are not empty, as Nägeli believed, but are filled with a highly hydrophilic colloid. The general presence in cell walls of the hydrophilic colloidal phosphatides discovered by Hansteen-Cranner is of undoubted importance in this respect. Other workers have suggested other colloidal substances. In young membranes this colloidal intermicellar substance may be of pectic nature. In young *Closterium* walls one can see the double refraction of the cellulose gradually appear and increase in the isotropic membrane (Frey). In cellulose walls an amorphous cellulose may form the colloidal matrix (Herzog). In cutinized and suberized membranes, it may be the cutin and suberin (Frey), and in lignified walls the lignin. That lignin is *between* the cellulose micellae and not *in* them is proven by the fact that lignified walls give the x-ray pictures of pure cellulose (Frey)."

During this same year a paper by Hess and co-workers¹²⁸ reported the presence of a nitrogenous foreign substance in ramie and cotton fibers which was found to have a high ash content and to swell strongly in pyridin. They stated that the material is frequently held fast during the purification of the fibrous mass and questioned whether or not it is arranged inside the fiber wall. This substance was found to be the bearer of the ash in the fiber, and an analysis of the ash showed that it was almost entirely calcium oxide.

These accumulated data were sufficiently impressive to warrant the modification of the micellar hypothesis of Nägeli, according to the suggestions of Frey⁷⁷ and Anderson.⁹ With the presence of a colloidal matrix between the cellulose crystallites, many of the observed physical and chemical properties of the membrane could be explained, and the objections to the hypothesis as a "working" conception largely overcome. During the development of these modifications the idea of the original hypothesis that the crystallites of cellulose are submicroscopic remained unchanged. The extensive studies of Ambrohn and Frey revealed no microscopically visible crystalline units below the fibril, and the x-ray diffraction analyses could furnish no conclusive evidence concerning the existence of a structural unit between the cellulose unit cell and the fibril. Spierer²⁴¹ reported in 1926 that fragmentation of the wall striations into "supernicellae" of microscopic dimensions had been observed by means of the Spierer lens. The optical properties of this lens were said to be of such a nature that both microscopic and ultramicroscopic structure of the wall were revealed. Seifriz^{235, p. 152} writes: "The supernicells seen with the Spierer lens are 0.5 to 0.7 μ in thickness and 1.2 μ in length. Such particles are above the lower limit of microscopic visibility by direct light, and are, therefore, not ultramicroscopic in the true sense, yet they are not visible with direct light; in this latter sense only are they ultramicroscopic. Lack of optical differentiation between particle and matrix makes dark-field observation necessary to show the particles." These studies with the Spierer lens were extended by Thiessen²⁵⁸ to various types of cellulosic material including coal. Clifford and Cameron⁴¹ questioned the optical properties of the lens and presented evidence to show that the supernicells in cell membranes described by Spierer, Seifriz, and Thiessen were artifacts. Although by this time, the existence of wall striations and of separable wall fibrils was evidenced from many types of study, the conception of the submicroscopic units, as the building blocks of the fibril, prevailed (Figs. 6a, b, c, d).

The existence of submicroscopic micellae in the cell membrane was, however, not without question. Fischer⁶⁶ commented upon the uncertainties as follows: "One sees upon an object a special optical effect, as for instance double refraction, and one is persuaded, upon the authority of Nägeli, that the material is made up of small parallel-arranged bodies of crystalline nature. Therein is the premise: *The objects of this internal structure lead to this special effect of double refraction.* Now nothing lies nearer than the converse: *This phenomenon of double refraction shows that such an inner structure must exist.* This, however, may be a fallacy; we cannot prove the matter experimentally; we cannot produce such a body which is made up of diminutive parallel arranged crystallites and then study with polarized light or x-rays, a body, of which we know, with full certainty, that it has this microstructure, because we ourselves have produced it."

Sponsler^{242, 243} avoided many of these structural difficulties through the development, in 1925 and 1926, of a conception of cell-membrane structure which would account for its known properties upon a molecular basis. In the course of his investigations he obtained the first approximate dimensions of the cellulose unit cell and expressed the belief that the diffraction data obtained from x-ray analysis of cellulose may be accounted for upon the basis of chains of cellulose unit cells of indefinite length, thus eliminating the necessity for consideration of micellar aggregates. In a later study of the growth of cross walls in certain algae,²⁴⁵ he found that the deposition of cellulose takes place in the form of molecular layers at the rate of 20 molecular layers per second. Sponsler and Dore²⁴⁷ developed more fully the conception of the cellulose chain structure, and Sponsler²⁴⁴ revised their conclusion regarding the nature of the union between glucose residues in favor of a chain structure which would accommodate the cellobiose linkage. Sponsler and Dore²⁴⁸ pointed out later, however, that the problem of accounting for the odd order reflections of the long identity period still remained unsolved. Staudinger,²⁵⁰ on the basis of viscosity measurements, likewise postulated the existence of very long chains of cellulose which he believed to be of sufficient size to warrant the name *macromolecule*. Hengstenberg and Mark,¹¹⁰ recognizing the existence of cellulose chains, questioned their indefinite length, however. They expressed the opinion in 1928 that the cellulose chains are comparatively short, and are arranged in the form of a bundle or micellar unit. Their x-ray measurements indicated crystalline dimensions of $50 \times 50 \times 500$ Å. These measurements were corroborated in 1930 by the x-ray analyses of Clark⁴⁰ and in the chemical analyses of Haworth and Machemer,¹⁰⁹ but in 1933 Sponsler²⁴⁴ suggested alternative interpretations of their data involving a long-chain rather than a micellar structure.

Carothers,³⁸ in a discussion of polymeric compounds, suggested a new type of organization of chain molecules in the walls of plant fibers in which the long axis of the chains is approximately parallel to the long axis of the fiber, with pronounced overlapping of the ends of the chains (Fig. 6e). In a review by Kratky¹⁵¹ the evolution of the most recent concept of cell-membrane structure, which has points in common with both micellar hypothesis and the chain hypothesis, is presented. The idea of *fringed micells* (Fig. 6f) is based upon the work of many authors and has been defined by Thiessen²⁵⁷ as follows: "The cellulose micelle is an ultramicroscopic mixed crystal of cellulose chains, differing in length. Ends of chains project beyond the micelle ends formed by shorter chains (fringed micelle). Because of the shorter filaments interposed in the micelle core the fringes have such large lateral distances that van der Waal's forces no longer hold them together. For this reason they tend to separate."

As shown in Fig. 6f, the chain molecules, according to this conception, overlap in such a way that in certain areas they are entirely regular. In other areas they are irregular and less dense. Alternation of these regular and irregular chain areas, in the fashion shown in Figs. 6g and h, results in the distribution of crystalline and

amorphous areas throughout the membrane—an interpretation in increasing demand as data concerning the heterogeneous physical and colloidal properties of cell membranes continue to accumulate. Freund and Mark⁷³ state, "All experimental evidence of the last years points in the direction that all high polymers in the solid state are complicated two (or even multi-) phase systems." The behavior of such systems during solution, coagulation, and orientation is shown diagrammatically in Fig. 6h.

The voluminous literature which has accumulated during the past twenty-five years upon the physical and chemical properties of plant-cell membranes cannot be adequately represented within the limits of this presentation. It must suffice to cite briefly only certain aspects of the experimental approach to an understanding of the complex problem, and certain conclusions which have been drawn from the data obtained. Various viewpoints of the structural elements within *micellae* were published between 1929 and 1939 by Staudinger and Singer,^{252, 249} Gerngross and co-workers,^{83, 84} Frey-Wyssling,⁸⁰ Kratky,^{149, 150} Mark and Meyer,¹⁶⁴ Guth and Rogovin,⁹⁷ and Sauter.²²⁰ In a paper presented before the members of the Society of Dyers and Colourists in 1932, Neale,¹⁸⁶ however, maintained that the conception of *micellae*, or separate units between glucose residues and the cotton fiber, is not necessary; that a discontinuous micellar structure does not explain phenomena such as axial shrinkage and lateral swelling; and that such a viewpoint necessitates an arbitrary distinction between inter- and intra-micellar swelling. In the discussion following Neale's presentation, Katz pointed out that the fact that cohesion is not destroyed when liquid penetrates into the interior of a body capable of swelling is perhaps one of the most surprising facts that we know about the phenomenon of swelling. He raised the question why, since a precipitate of barium sulfate, for instance, does not swell, every precipitate of cellulose, starch, protein, etc. shows swelling and cohesion? Fischer⁶⁶ had made a similar comment in 1927, using colloidal platinum as an example of a non-swelling precipitate. To these questionings Khouvine¹⁴² added the comment, in 1934, that an attempt to define the word *cellulose* merely serves to remind us that it is a substance which we are not able to crystallize, which has no fusion point, which will not dissolve in ordinary chemical solvents, whose structural formula has been somewhat evasive, and whose molecular weight is definitely uncertain.

Many of these difficulties were avoided by the development of new trends in physical-chemical investigations of natural "high polymeric" organic substances, clearly described in 1930 by Meyer and Mark.^{172, Chap. 5} They pointed out that while the usual goal in classical organic chemistry is the development of a structural formula which would lead to knowledge of a method of synthesis, one is not satisfied with this in the study of high polymers; that it throws too little light upon the mechanical properties of these important substances; and that the present trend in physical chemistry is to model the structural formulas of organic chemistry in a way which is accurately descriptive of the size and form of the molecule and is also representative of the physical characteristics of the crystalline and fluid combinations under consideration. Beginning with the structural conception of the molecules of such a substance as cellulose or starch (Fig. 7), hypotheses were to be formulated as to their relative positions and the forces operating between them, and models were to be constructed which, if possible, would correlate with the characteristics of the substances. This method of approach has led to the current conception of plant-cell membrane structure upon a molecular basis. Before discussing concurrent developments in the field of cellulose analysis, it may be well to repeat these general results, as applied to cell membranes, summarized by Frey-Wyssling⁸¹ in 1938: "A revision of the Nägeli hypothesis of discontinuous cellulose micellae was found to be necessary. Evidence was found of a system of connected cellulose threads or layers. Cellulose, in the form of long, chain-like molecules formed a skeletal framework.

The molecular weight and length of the chains are not definitely known. They give a crystalline x-ray pattern, but are never seen in crystalline form. They are insoluble in all ordinary chemical solvents, but in reagents which will throw them into a viscous matrix, their viscosities show that a fairly close relation exists between the strength of the whole fiber and the length of the cellulose chain molecules; maximum strength is believed to be reached in chains of about 2000 glucose residues." These concepts were quickly adapted to the interpretation of the behavior of industrial materials.^{99, 87}

FIGURE 7. Structural models (after Haworth).

In the meantime, data of various types were accumulating in other laboratories which were to lead to different conceptions of membrane structure. Boehm²⁶ reported in 1933 that woods or woody materials could be disintegrated and remade by using as a binder the *non-cellulosic* material, which bonds the fibers in the original wood, resulting in a product with the original strength of wood and with fibers so oriented that expansion and swelling were greatly reduced. Butler³⁵ found the crude fiber content of the cell walls of certain marine algae sometimes used as cattle food, fertilizer, and a source of nitrogen, to be very low. In only one instance was it over 5 per cent (*Fucus* 5.21, *Laminaria* 3.61, *Porphyra* 2.75, *Chondrus* 2.15, *Gigartina* 2.05, *Rhodomenia* 1.50). Protein, ash, and other carbohydrates constituted the greater part of these sturdy membranes of interesting physical and colloidal properties. Russel-Wells²¹⁴ likewise established the presence of cellulose in certain red

and brown algae (*Corallina officinalis*, *Bostrychia scorpioides*, *Chondrus crispus*, *Rhodymenia palmata*, *Laminaria saccharina*, *L. digitata*, *Fucus serratus*, *F. vesiculosus*, *Ascophyllum nodosum*, and *Pelvetia canaliculata*). Guilliermond⁹⁶ reported the observation of granules of various sorts, both at rest and in motion in the cells of *Saprolegnia*, by means of both ordinary and polarized light; in the epidermal cells of tulip and iris he found both granules and chains of granules. Bonner and Heyn²⁷ prepared suspensions of cell-wall particles of oat coleoptiles by grinding the membranes in distilled water or 5 per cent NaCl. Heavier cell-wall fragments were removed by repeated centrifuging in distilled water. The particles were found to be rich in pectin and protein. It was found that the protein was tightly bound because, after the removal of the pectic material with ammonium oxalate, hot dilute HCl and hot dilute NaOH, the protein reaction of the particles and their cataphoretic behavior were not affected. These observations were of special interest in the light of the studies of "protective colloids" by Loeb,¹⁵⁸ who found that paraffin particles coated with gelatin behaved as though they were gelatin; by Reinders and Bendien,²⁰⁶ who found that a gold sol sufficiently protected with protein can exhibit positive or negative signs of charge depending upon the pH value of the solution, and suggested that besides the formation of a protective colloid, the possibility exists that the molecules of protein are oriented at the interface; and by Freundlich and Abramson,⁷⁴ who found that the cataphoretic behavior of quartz particles, when coated with gelatin, is typical of gelatin.

In 1934 Dauphine⁵² reported the intimate association of *proteins* with *cellulose* and *pectic materials* in the membranes of *Aucuba japonica*. Microchemical tests for these three substances were made in untreated membranes, after prolonged treatment with sodium hypochlorite. The ruthenium red reactions of pectic materials and the $\text{H}_2\text{SO}_4 + \text{I}_2\text{KI}$ reactions of cellulose were not affected by the hypochlorite treatment. On the other hand, protein reactions were obtained only in untreated material, in both cytoplasm and cell membranes. In the fresh material the protein reactions in the cytoplasm and the membrane differed only in intensity—they were fainter in the cytoplasm. In the triangular areas at the corners of the cells there were accumulations of granular material which, likewise, became brown in the xanthoproteic reaction. These observations of granular cellular inclusions (Guilliermond) of protein reactions of cell-wall particles (Bonner and Heyn and Dauphine) and of the functioning of protective colloids (Loeb, Reinders and Bendien, and Freundlich and Abramson) are reminiscent of the earlier observations of Strasburger,²⁵⁴ who saw "protein granules" (*microsomes*) in the cell protoplasm which were used up in the formation of the cell membrane, and of Wiesner²⁶⁸ who found that the "protein granules" (*dermatosomes*) in the protoplasm "in some mysterious manner" were changed into cellulose after they were deposited in the cell membrane.

In this same year Farr and Eckerson⁶² reported the presence of ellipsoidal cellulose particles ($1.1 \times 1.5\mu$) in the cytoplasm of young cotton fibers, of sporangiophores of *Aspergillus*, and of cells of *Spirogyra*, *Oedogonium*, and *Valonia*. These particles are separate or joined end-to-end in single rows (Figs. 8a, b, c). The double refraction of the particles is clearly visible in the fresh mounts (Fig. 9a), both separate and in the chains. The application of iodine, in making the $\text{H}_2\text{SO}_4 + \text{I}_2\text{KI}$ test for cellulose, resulted in a reaction with the cytoplasmic protein on their surfaces, giving a yellow-brown color. At this stage of the reaction one might conclude, as had Strasburger and Wiesner, that the particles are protein. This protein precipitation upon the particle surface was prevented, however, by pretreatment of the microscopic mount with 10 per cent KOH for 5 minutes or 4 per cent NaOH for 10 to 15 minutes: P.¹⁹⁰ "After washing, a drop of iodine solution is allowed to run under the cover glass; then a drop of the sulfuric acid is added at the edge of the cover glass. In most of the fibers the chains of particles are now a clear cellulose blue, standing out sharply from the almost colorless background of the cell" (Figs. 9b, c). The re-

FIGURE 8. A. Separate cellulose particles in the protoplasm of a young cotton fiber (X 725). B. Early stage of fibril formation in a young cotton fiber (X 725). C. Cell membrane of the cotton fiber after deposition of cellulose fibrils in spiral arrangement in the fiber wall (X 725).

fractive indices determined by the immersion method are 1.565 lengthwise and 1.530 crosswise.

Even in the young, undried cotton fibers considerable difficulty is experienced in removing a coating of material from the cellulose particle surface which stains with ruthenium red. Concerning more mature fibers, the authors state,^{62, p. 191} "When a nearly mature fiber from an unopened boll is put into a 4 per cent solution of sodium hydroxide, the separation of the fiber into fibrils and of the fibril into particles does not occur simultaneously. First there is the separation of the fiber into fibrils by

FIGURE 9. A. Cellulose particles are doubly refractive in polarized light (X 2000). B. Separate cellulose particles from protoplasm of a living cell swell and turn blue in sulfuric acid and iodine (X 1400). C. Cellulose fibrils from mature cell membrane show swelling and blue coloration of particles in sulfuric acid and iodine (X 1400). D. Mature cotton fiber treated with phosphoric acid and iodine. Swelling of cementing material and swelling and blue coloration of cellulose particles produce "honeycomb" appearance when particles are not obscured (X 1400).

partial solution of the pectic substance surrounding them. Then, an hour or more later, the fibril begins to separate into particles. A dry fiber from an opened boll requires much longer treatment to bring about the same separation."

Concerning the identification of the chemical nature of this film of material upon the particle surface, the authors state,^{62, p. 191} "Although no chemical analyses of the galacturonic acid content were made, the solubility, non-double refraction, and the staining with ruthenium red are properties like those of the pectic substance in apple fruits and other tissues which have been analyzed. . . . It is not the water-soluble pectin, but whether it is pectic acid, a pectate, or protopectin is not known." Continued study of this material from many types of plant cells led to the statements in 1937 by Farr,^{57, p. 988} "Its hydrophilic properties are, in general, those described by botanists of the last century as characteristic of 'pectic' materials. It is very unlikely that in final chemical analysis all of its basic constituents will meet the requirements of the modern chemical concept of pectic substance."; and:^{58, p. 229} "Many of its properties are similar to those of the viscous colloidal phase of the cytoplasm in which the particles are suspended. It may be nothing more than an adhering layer of this mixture whose chemical properties themselves are not understood." The accuracy of this conception has been made clear in a more recent investigation by Farr,⁶¹ in which the stages of formation of the cellulose particles in living cotton fibers and certain marine algae have been observed and described.

In the original paper the behavior of the cellulose particles during cell-membrane formation is described as follows:^{62, p. 192} "From direct observation we may conclude, therefore, that the pectic-coated cellulose particles distinguishable in the living cytoplasm may exist singly or in chains; that toward the center of the lumen the single and short chain types of arrangement predominate; that as the wall is approached the chains become longer; and that a single chain of closely appressed particles forms a single fibril of the fiber wall." The spiral arrangement of these fibrils in the wall of the mature cotton fiber is shown in Fig. 8c.

Later studies by Farr and Eckerson⁶³ led to a method of "purification" of comparatively large quantities of cellulose particles, without evidence of degradation, by treatment with hydrochloric acid. Material was thus made available for study of additional particle properties. Before the end of the same year confirmation of the cellulose nature of these particles had been obtained by Farr and Sisson⁶⁴ by means of x-ray diffraction analyses (Fig. 10). After continued study a method was devised by Sisson,²³⁷ which led to the identification by the same technique, of the crystalline cellulose in young cotton fibers at ages corresponding to those reported earlier by Farr and Eckerson.⁶² The method involved, at least a partial removal of the amorphous material from the surfaces of the particles used in the x-ray diffraction analysis. In discussing this work later Sisson^{240, p. 196} states, "Comparative x-ray and microscopic studies indicate that the crystalline pattern of cellulose arises from the cellulose particle, which shows double refraction in polarized light. Furthermore, the size of the particle ($1.1 \times 1.5\mu$) is small enough to give the Debye-Scherrer patterns observed. It is unnecessary to assume crystalline units smaller than the particle, since powder patterns are obtained whenever the crystals of the diffraction sample become smaller than about 5μ .

"There is also reason to believe that the amorphous pattern present in the x-ray diagram of cellulose fibers may be partly accounted for by the non-doubly refractive material which may be observed on the surface of the particles. This assumption is based largely upon purification studies. . . . Extraction of these young fibers with organic solvents removes a fraction which gives an x-ray pattern characteristic of a waxy material; extraction with ammonium oxalate, a fraction which gives a pattern characteristic of a pectic material; and extraction with hot dilute alkali, a fraction which gives an amorphous pattern. After these extractions the residue gives only the crystalline diffraction pattern of cellulose, upon which there is superimposed a

weak amorphous pattern. Microscopic examination shows this residue to contain cellulose particles covered with a thin coat of non-doubly refractive material, the other non-cellulosic materials originally present in the young fiber having been removed by the purification process. . . . These preliminary studies, therefore, would indicate that the amorphous portion of the cellulose membrane diffraction diagram may arise from two more or less overlapping sources. One source is that of

FIGURE 10. X-ray diagrams of: A. ground cotton; B. *cellulose particles* prepared from cotton fibers by treatment with HCl (sp. gr. 1.19); C. paralleled cotton fibers; D. paralleled ramie fibers. All diffraction lines are those of *native* cellulose. The purified cellulose in the form of cellulose particles is sharper than that of ground cotton due to the removal of amorphous materials and the ramie shows a more perfect alignment of fibrils with respect to the fiber axis than cotton.

the non-cellulosic materials which often may be removed by the usual purification processes without destroying the membrane structure. The other is that of an as yet unidentified material which is more intimately associated with the crystalline cellulose, and which apparently plays the role of a cementing material which holds the particles together."

Further evidence of the chemical complexity of this inter-particle material has been shown by Compton and Haver.^{45, 44} In more recent articles, describing the formation of cellulose particles in the chloroplasts of *Halicystis* and in the colorless

FIGURE 11. Column A. Stages in development of the chloroplast of *Halicystis* showing cellulose ring and cellulose particle formation (X 770). Column B. Stages in starch grain formation in the chloroplasts of the cotton plant (X 770). Column C. Cellulose particle formation in the colorless plastids of the cotton fiber by a process of successive ring formation and fragmentation essentially similar to the mechanism of cellulose formation in *Halicystis* (X 770).

plastids of the cotton fiber, Farr^{60, 61} has presented additional evidence not only as to its complexity in any given membrane but also as to the high degree of variability in various types of plant-cell membranes. In the chloroplast of *Halicystis** the

* A complete report of the studies of cellulose particle formation in *Halicystis* is to be published in a forthcoming issue of the Contributions from Boyce Thompson Institute.

formation of cellulose particles takes place through the fragmentation of cellulose rings of varying diameter but equal thickness. These rings are produced successively in the outer regions of the plastid plasma during the normal growth of the chloroplast. The membrane of the chloroplast finally breaks, and the entire plastid contents, including the cellulose particles and the green plasma, are deposited on the inner surface of the cell membrane in the course of the formation of a new membrane lamella. The various stages of cellulose ring formation and ring fragmentation to form cellulose particles can be followed microscopically, although the green chlorophyll in the plastid plasma tends to obscure such minute structural details (Fig. 11a). The cellulose rings and cellulose particles in the chloroplast of *Halicystis* react microchemically as mercerized cellulose, as indicated earlier by Sisson²³⁸ in connection with cellulose particles in *Halicystis* membranes.

The mechanism of *native* cellulose particle formation in colorless plastids (Fig. 12a) of the cotton fiber is essentially similar to the mechanism of *mercerized* cellulose formation in the chloroplast of *Halicystis*^{61, p. 191} "In the developing cotton fiber the cellulose-forming plastid is rendered nearly invisible by the similarity in its refractive index and that of the cytoplasm which surrounds it. Measurements show that both are between 1.33 and 1.34. While the cellulose particles with refractive indices of 1.565 (lengthwise) and 1.530 (crosswise) are held within the plastid membrane, they are very effectively obscured. When they are freed by the bursting of the membrane . . . they attain a degree of visibility which made possible their identification in 1934. Their complete development within a specialized organ such as a plastid accounts fully for their sudden appearance, full formed, in the cytoplasm, prior to the assumption of their final role in the formation of the cell membrane" (Figs. 12b, c; Fig. 11c; Figs. 8a, b, c).

Among the many immediate problems created by these new findings none was more important than the determination of the method of cellulose formation in plant cells in which both starch and cellulose are formed. In the cotton fiber cellulose alone is produced. A study of leaf, stem, and boll-wall cells of the cotton plant has revealed that while starch is formed in chloroplasts, usually lying near to the surface of the protoplast, cellulose is formed in colorless plastids which are located in the interior regions of the protoplast (Fig. 12d). It can be seen that these two closely related carbohydrates probably came into existence simultaneously, in separate plastids, in the same cell. A comparison of the stages of cellulose ring and cellulose particle formation in the chloroplasts of *Halicystis* and in the colorless plastid of the cotton fiber is shown in Figs. 11a and c, and these in turn can be compared with the stages of starch formation in Fig. 11b.

These observations of cellulose-particle formation in the living cells of *Halicystis* and the cotton fiber leave unquestionable the growing evidence of the chemical complexity of the inter-particle material. In *Halicystis* the entire plastid content apparently enters into the formation of the membrane lamellae. Along with any cytoplasmic material which may be carried with it, the plastid plasma with all of its components, including the chlorophyll, makes up the *cementing material* of the newly deposited membrane layers. Frequently entire green chloroplasts are found imbedded in the wall (Fig. 4c), a phenomenon reported first by Correns⁴⁶ in *Valonia* and found repeatedly in both *Halicystis* and *Valonia* membranes by the author. Their presence in the membranes was not understood until the relation of the chloroplasts in these cells to cell-membrane formation had been revealed. The absence of information always invites speculation, and many interesting suggestions have been forthcoming. Sisson^{240, p. 195} states, "Since many non-cellulosic materials are so closely associated with cellulose during its formation in the cytoplasm, it is possible that there may be a sort of mixed crystallization of the cellulose with non-cellulosic materials at the surface of the particle. This is suggested by comparative x-ray and microscopic studies of a number of cellulose membranes, which indicate that when-

ever a large amount of non-doubly refractive material may be observed on the surface of the cellulose particle, the equatorial diffraction lines are always broad and unresolved. If the surface of the cellulose particle, on the other hand, is observed to be comparatively free from non-doubly refractive material, then the diffracting lines are sharp and more clearly resolved. One would not expect the surface of the cellulose particle, molecularly speaking, to be as smooth as the surface of crystals which are built up of small molecules held together by secondary valences. It is not unreasonable to assume that the long primary-valence cellulose chains would protrude at the surface and especially at the end of the particle to give a fringe structure.

FIGURE 12. A. Young cotton fiber showing barely visible cellulose-forming colorless plastids (X 1155). B. Cellulose-forming plastid removed from cotton fiber to improve visibility (X 1095). C. Reaction of cellulose-forming plastid to sulfuric acid and iodine showing plastid plasma escaping from plastid membrane and blue coloration of cellulose particles in plastid plasma (X 1095). D. Single cell from a cotton leaf showing a chloroplast, a nucleus, and a cellulose-forming plastid in focus (X 1095).

Such a structure would not only greatly increase the effective particle surface, but also permit a more permanent end-to-end union of the particles to form fibrils and allow the polar hydroxyl groups of the protruding chains to become closely associated with other hydrophilic cytoplasmic constituents during particle formation." Likewise Compton,^{44, p. 418} in commenting on the presence of pectic material in the cotton-fiber membrane, states: "The importance of the proven existence of at least one polyuronide in cotton fibers lies in the possibility that the intercrystalline, amorphous, fiber phase is composed of various molecular modifications intermediate between those of these substances and the true cellulose molecule."

In the light of our present knowledge of the early stages of cellulose particle formation, these and many other constructive suggestions are transferred from a state of postulation to one of experimentation. Cellulose-forming plastids can be made to give up their cellulose rings at the many stages of development from the liquid, through the gel, to the final crystalline state (Fig. 13); fractionations of plastid plasma can be attempted by electrophoretic techniques such as those developed by Tiselius;²⁵⁹ comparisons of these fractions with fractions of peripheral cytoplasm immediately before and after deposition in a newly formed wall lamella might lead to definite knowledge of the contribution to cell wall constituents of the basic cytoplasm of the cell which surrounds the plastids. And, in the course of these investigations we might learn more of the important and unknown properties of the many types of microscopically visible structures which are distributed throughout the continuous colloidal ground substance in which the various activities peculiar to the life processes of a cell take place.
